**Abstract.** We present a global distribution of surface methane (CH<sub>4</sub>) emission estimates for 2000-2012 using CarbonTracker Europe-CH<sub>4</sub> (CTE-CH<sub>4</sub>) data assimilation system. In CTE-CH<sub>4</sub>, anthropogenic and biospheric CH<sub>4</sub> emissions are simultaneously estimated based on constraints of global atmospheric in situ CH<sub>4</sub> observations. The system was configured to either estimate only anthropogenic or biospheric sources per region, or to estimate both categories simultaneously. The latter increased the number of optimizable parameters from 62 to 78. In addition, the differences between two numerical schemes available to perform turbulent vertical mixing in the atmospheric transport model TM5 were examined. Together, the system configurations encompass important axes of uncertainty in inversions and allow us to examine the robustness of the flux estimates. The posterior emission estimates are further evaluated by comparing simulated atmospheric CH<sub>4</sub> to surface in situ observations, vertical profiles of CH<sub>4</sub> made by aircraft, remotely-sensed dry air total column-averaged mole fractions (XCH<sub>4</sub>) from the Total Carbon Column Observing Network (TCCON), and XCH<sub>4</sub> from the Greenhouse gases Observing SATellite (GOSAT). The evaluation with non-assimilated observations shows that posterior XCH<sub>4</sub> is better matched with the retrievals when the vertical mixing scheme with faster interhemispheric exchange is used. Estimated posterior mean total global

30  
35

emissions during 2000-2012 are  $516 \pm 51$  Tg CH<sub>4</sub> yr<sup>-1</sup>, and increases by 18 Tg CH<sub>4</sub> yr<sup>-1</sup> from 2000-2006 to 2007-2012. The increase is mainly driven by an increase in emissions from South American temperate, Asian temperate and Asian tropical TransCom regions. In addition, the increase is hardly sensitive to different model configurations ( $< 2$  Tg CH<sub>4</sub> yr<sup>-1</sup> difference), and much smaller than suggested by EDGAR v4.2 FT2010 inventory (33 Tg CH<sub>4</sub> yr<sup>-1</sup>), which was used as prior anthropogenic emission estimates. The result is in good agreement with other published estimates from inverse modelling studies (16-20 Tg CH<sub>4</sub> yr<sup>-1</sup>). However, this study could not conclusively separate a small trend in biospheric emissions (-5 to +6.9 Tg CH<sub>4</sub> yr<sup>-1</sup>) from the much larger trend in anthropogenic emissions (15-27 Tg CH<sub>4</sub> yr<sup>-1</sup>). Finally, we find that the global and North American CH<sub>4</sub> balance could be closed over this time period without the previously suggested need to strongly increase anthropogenic CH<sub>4</sub> emissions in the United States. With further developments, especially on the treatment of the atmospheric CH<sub>4</sub> sink, we expect the data assimilation system presented here will be able to contribute to the ongoing interpretation of changes in this important greenhouse gas budget.

## 1 Introduction

Methane (CH<sub>4</sub>) is a greenhouse gas with Global Warming Potential 28 times that of carbon dioxide (CO<sub>2</sub>) on a 100-year time horizon (Azar and Johansson, 2012; Boucher 2012; Peters *et al.*, 2011; Reisinger *et al.*, 2010). Following years of almost no growth during 1999-2006, atmospheric CH<sub>4</sub> started to increase again in 2007 (Rigby *et al.*, 2008; Dlugokencky *et al.*, 2009). The growth rate of globally averaged atmospheric CH<sub>4</sub> from 2007 to 2012 was 5.7 ppb per year, which represents a significant change to the global CH<sub>4</sub> budget. The mechanisms behind this increase are still debated (e.g. Heiman, 2011; Dlugokencky *et al.*, 2011; Dalsøren *et al.*, 2016).

Methane is mainly emitted by anthropogenic activities and natural biogenic processes, followed by minor contributions from biomass burning, ocean, inland water bodies and geologic activities. The main anthropogenic sources are fugitive emission from solid fuels, leaks from gas extraction and distribution, agriculture, and waste management. Anthropogenic CH<sub>4</sub> emissions account for more than half of total CH<sub>4</sub> emissions from land and ocean (Kirschke *et al.*, 2013; Saunio *et al.*, 2016). Anthropogenic CH<sub>4</sub> emissions have increased significantly since pre-industrial times largely due to the heavy use of fossil fuels, but also due to the increase in ruminants, landfills and rice fields corresponding to the increase in human population (Ghosh *et al.*, 2015). This has resulted in a steep increase in the amount of CH<sub>4</sub> in the atmosphere. Previous studies suggest that anthropogenic CH<sub>4</sub> emissions did not increase significantly, or even decreased, during the 1980s and 1990s (Bousquet *et al.*, 2006; Dlugokencky *et al.*, 1998), which may have been one of the cause of stabilization of the atmospheric CH<sub>4</sub> burden from 1999-2006 (Dlugokencky *et al.*, 2003). Although the changes in CH<sub>4</sub> emissions in more recent years have not been satisfactorily explained, recent studies indicate an increase in the CH<sub>4</sub> emissions from biogenic sources (Schaefer *et al.*, 2016; Schwietzke *et al.*, 2016; Nisbet *et al.*, 2016), and large CH<sub>4</sub> emissions from the tropics in the 21<sup>st</sup> century (Saunio *et al.*, 2016). Methane emissions from natural wetlands account for around 30% of total CH<sub>4</sub> emissions (Kirschke *et al.*, 2013). Wetlands

and peatlands are the major sources of natural biospheric CH<sub>4</sub> emissions. Most peatlands are in high northern latitudes, whereas large wetland areas are located in the tropics. Emissions from natural biospheric sources have strong seasonal and interannual variability (Spahni *et al.*, 2011), contributing substantially to seasonal and interannual variability in the atmospheric CH<sub>4</sub> burden (Meng *et al.*, 2015). In addition, photochemical reaction with hydroxide (OH) in the troposphere, the major sink of  
5 CH<sub>4</sub>, has strong effects on the annual cycle of atmospheric CH<sub>4</sub>.

Attributing the observed changes in CH<sub>4</sub> burden to changes in emission sources is difficult because variations in CH<sub>4</sub> emissions from both anthropogenic and biogenic sources are not sufficiently understood. In addition, large uncertainty remains on changes in the lifetime of atmospheric CH<sub>4</sub>. Montzka *et al.* (2011) found an increase in OH concentrations in the beginning of  
10 the 21st century, followed by a decrease in OH concentrations after 2004-2005. More recently, Ghosh *et al.* (2016) and Dalsøren *et al.* (2016) also obtained a decrease in the CH<sub>4</sub> lifetime in their simulations. McNorton *et al.* (2015) showed that although interannual variability of OH may be small, small changes in OH concentrations could lead to significant changes in CH<sub>4</sub> concentrations. On the other hand, Rigby *et al.* (2008) suggested that a decrease in tropospheric OH concentration could be one of the reasons for the increase in atmospheric CH<sub>4</sub> after 2007. The uncertainty in changes in OH concentrations and its  
15 relation to the CH<sub>4</sub> burden still remains large (Prather *et al.*, 2012), and need to be further assessed.

Several inverse models have been developed to estimate CH<sub>4</sub> emissions and their contribution to the atmospheric CH<sub>4</sub> burden (e.g. Bousquet *et al.*, 2006; Bruhwiler *et al.*, 2014; Houweling *et al.*, 2014; Fraser *et al.*, 2013; Meirink *et al.*, 2008). Emission estimates vary among models (e.g. Kirschke *et al.*, 2013; Locatelli *et al.*, 2013; Bergamaschi *et al.*, 2015; Tsuruta *et al.*, 2015)  
20 as these inverse systems rely on specific choices in the design of the inverse problem. Inputs, such as prior emission fields and observations, and the transport model used in inversions play a major role in regional and continental emission estimates. Depending on the optimization method and available information, it may or may not be possible to derive information at small spatial scales. For example, the computational cost in adjoint models (Bergamaschi *et al.*, 2015; Belikov *et al.*, 2013; Houweling *et al.*, 2014; Meirink *et al.*, 2008) is not highly dependent on the number of scaling factors used to ‘scale’ the prior  
25 (first guess of emission estimates) in order to get optimized (posterior) emissions, i.e. such models have the ability to perform grid-scale optimization globally. The computational cost in some other methods, such as Thompson and Stohl (2014) and Zhao *et al.* (2009) depends on the number of scaling factors as the method directly uses their very large covariance matrix. In that case, grid-scale optimization is possible without any asymptotic assumptions, but only for regional domains, because the dimensions of the covariance matrix for a global domain become too large, even for current computational capability.  
30 Ensemble Kalman filter (EnKF) based systems (Bruhwiler *et al.*, 2014; Tsuruta *et al.*, 2015) typically have smaller computational limitations related to the number of scaling factors. By representing the state covariance matrix with a limited number of samples of the state (ensemble members), the computational cost depends mostly on the number of ensemble members. The trade-off in these methods comes as an approximation of the cost function minimum that only improves with more ensemble members, and thus more cost.

The simultaneous estimation of biospheric and anthropogenic contributions to the CH<sub>4</sub> budget is more difficult when both emissions are in the same location. Prior information from an underlying ecosystem distribution map can be useful, as it defines the location of the biospheric sources. CH<sub>4</sub> emissions also depend on soil properties (Spahni *et al.*, 2011), and therefore the distribution of wetlands and their inundation extent can be used as prior information. This approach has the advantage that emission estimates from difference source categories and ecosystem types can be optimized separately by the application of different scaling factors. However, it is known that the spatial distribution of CH<sub>4</sub> sources relies heavily on these prior estimates, and that emissions cannot be assigned to regions outside of the predefined source regions. If the distribution in the prior or the ecosystem map is incorrect, the emission estimates would not be optimized appropriately. This approach was implemented in Tsuruta *et al.* (2015), and will be evaluated further in this study.

In this study, we examine emission estimates for 2000-2012 from CarbonTracker Europe-CH<sub>4</sub> (CTE-CH<sub>4</sub>) with three configurations in an attempt to report a more meaningful mean and uncertainty range than those from only one simulation. CTE-CH<sub>4</sub> is a version of the European branch of CarbonTracker data assimilation systems (Peters *et al.*, 2005; Peters *et al.*, 2010; van der Laan- Luijkx *et al.*, 2015). The inversions were designed to examine uncertainties related to parametrization in the system, as well as using different vertical transport schemes. The choice reflects the finding by Locatelli *et al.* (2013) that the regional flux estimates can differ by up to 150% on a grid-scale depending on the transport model. On the larger scale, one important property is the inter-hemispheric (IH) exchange rate, which has strong effects on the north-south gradient (Locatelli *et al.*, 2013). The strong influence of the vertical mixing scheme was also shown by Olivié *et al.* (2004), which will be explicitly examined in this study. For the evaluation, simulated atmospheric CH<sub>4</sub> was compared with data from in situ observation sites to evaluate the statistical consistency of the CH<sub>4</sub> emission estimates. Furthermore, non-assimilated observations from aircraft campaigns in Europe, and ground- and satellite-based retrievals of dry air total column-averaged mole fractions (XCH<sub>4</sub>) from Total Carbon Column Observing Network (TCCON) and Greenhouse gases Observing SATellite (GOSAT) were used to evaluate vertical and long-range transport. Details of the data assimilation system and its designs are described first in Section 2, as well as the observations used to drive and evaluate the estimates. The evaluation is discussed in Section 3.1, 3.2 and 3.3, followed by the range of global and regional CH<sub>4</sub> budget estimates (Section 3.4). Results are discussed in Section 4, comparing them to other recent estimates, and summarized in conclusions (Section 5).

## 2. Methods and Datasets

### 2.1 CTE-CH<sub>4</sub>

CTE-CH<sub>4</sub> is an atmospheric inverse model that optimizes global surface CH<sub>4</sub> emissions region-wise based on an ensemble Kalman filter (EnKF; Evensen, 2003) used to minimize a cost function:

$$J = (\mathbf{x} - \mathbf{x}^b)^T \mathbf{P}^{-1}(\mathbf{x} - \mathbf{x}^b) + (\mathbf{y} - H(\mathbf{x}))^T \mathbf{R}^{-1}(\mathbf{y} - H(\mathbf{x})) \quad (1)$$

$$\mathbf{E} = G(\mathbf{x})\mathbf{E}^b \quad (2)$$

where  $\mathbf{x}$  (dimension N) is a state vector that contains a set of scaling factors that multiply the CH<sub>4</sub> surface emissions ( $\mathbf{E}$ , dimension 360×180, latitude×longitude degrees) that we wish to optimize, starting from a prior estimate of these emissions ( $\mathbf{E}^b$  [360×180]) and scaling factors  $\mathbf{x}^b$  [N].  $\mathbf{P}$  [N×N] is the covariance matrix of the state vector,  $\mathbf{y}$  (dimension M) is a vector of atmospheric CH<sub>4</sub> observations,  $\mathbf{R}$  [M×M] is a covariance matrix of the observations  $\mathbf{y}$ , and  $H$  is an observation operator [M×N]. The operator  $G$  transforms the regionally estimated scaling factors  $\mathbf{x}$  to a 1°×1° global map, which are used to scale prior emissions  $\mathbf{E}$ . The cost function in Eq. (1) is minimized using an ensemble Kalman filter (EnKF) (Evensen, 2003) with 500 ensemble members, and the TM5 chemistry transport model (Krol *et al.*, 2005) was used as an observation operator that transforms emissions  $\mathbf{E}$  into simulated atmospheric CH<sub>4</sub> ( $H(\mathbf{x})$ ). The emissions  $\mathbf{E}$  were optimized weekly, with an assimilation window smoother length of five weeks.

In this study, anthropogenic and biospheric emissions were optimized, while emissions from other sources (fire, termites, and ocean) were not optimized (see Section 2.3). The optimal weekly mean CH<sub>4</sub> fluxes ( $F_{tot}$ ), in region  $r$  and time (week)  $t$ , were calculated as follows:

$$F_{tot}(r, t) = \lambda_{bio}(r, t) \times F_{bio}(r, t) + \lambda_{anth}(r, t) \times F_{anth}(r, t) + F_{fire}(r, t) + F_{term}(r, t) + F_{oce}(r, t) \quad (3)$$

where  $F_{bio}$ ,  $F_{ant}$ ,  $F_{fire}$ ,  $F_{term}$ ,  $F_{oce}$ , are the prior emissions from the biospheric, anthropogenic activities, fire, termites and ocean, respectively.

The optimization regional definition of CTE-CH<sub>4</sub> is defined based on modified TransCom (mTC) (Fig. 1) and land-ecosystem regions (Fig. S4). Land-ecosystem regions in a 1°×1° grid were defined based on Prigent *et al.* (2007) and Wania *et al.* (2010), as in the LPJ-WHyME vegetation model (Spahni *et al.* 2011), and contain six land ecosystem types (LET): inundated wetland and peatland (IWP), wet mineral soil (WMS), rice (RIC), anthropogenic land (ANT), water (WTR) and ice (ICE). Large lakes, the Mediterranean Sea, and other large bay areas were defined as WTR, similarly to Peters *et al.* (2007). ICE corresponds to the ice region in the mTC definition. The remainder of the land-ecosystem regions were defined according to the fraction of IWP, WMS and RIC used in LPJ-WHyME. To limit the number of degrees of freedom (d.o.f.), only one dominant LET was assigned to each grid cell. In the following cases, the LET with the largest fraction was chosen. For grid cells where the fraction of IWP, WMS or RIC was larger than 0.1, either IWP, WMS or RIC was assigned. IWP or WMS was assigned for grid cells where the fraction of IWP or WMS were smaller than 0.1, and the prior anthropogenic emission estimates (EDGARv4.2 FT2010, see Section 2.3) including emissions from rice fields were zero. Furthermore, if the LPJ-WHyME biospheric emission estimates exceeded the EDGARv4.2 FT2010 emission estimates by more than 200%, either IWP or WMS was assigned. However, if the EDGARv4.2 FT2010 emission estimates were much larger than the LPJ-WHyME biospheric emission estimates, either ANT, RIC or WTR was assigned.

In one of the two model configurations referred to as  $L^{62}$  (see also Table 1 for an overview of configurations), anthropogenic emissions were optimized in optimization regions where LET are RIC, ANT or WTR (i.e.  $\lambda_{bio}(r, t) = 0$ ), and biospheric emissions were optimized in optimization regions where LET are either IWP or WMS (i.e.  $\lambda_{anth}(r, t) = 0$ ). This mutually exclusive approach resulted in 28 biospheric regions and 34 anthropogenic optimization regions, i.e. 62 scaling factors  $\lambda(t) = (\lambda_{bio}(t), \lambda_{anth}(t))$  to be optimized per week globally. This number of scaling factors was smaller than theoretically expected (20 mTCs  $\times$  5 land-ecosystem regions = 100 scaling factors) because some mTCs contain less than five ecosystems types. In the second configurations referred to as  $L^{78}$ , both  $\lambda_{bio}(r, t)$  and  $\lambda_{anth}(r, t)$  were optimized in each optimization region. In that case, the regional definition of the scaling factors for biospheric emissions was based on the combination of mTCs and land-ecosystem regions, but ocean as one region instead of five (i.e. 58 biospheric regions). The mTCs (20 regions) were used for the anthropogenic emissions. This resulted in 78 scaling factors to be optimized per week globally. Note that scaling factors were optimized based on sensitivities in the EnKF (represented in Kalman Gain matrix), and thus there is no explicitly prescribed system to choose which of the scaling factors ( $\lambda_{bio}(r, t)$  or  $\lambda_{anth}(r, t)$ ) are adjusted more in each optimization region. A discussion of the application of land-ecosystem distribution maps and their effect on  $CH_4$  emission inversions for a short period during summer 2007 is also included in the *Supplementary Material* of this study.

For the prior uncertainty, variance of the scaling factors was set to 0.8 for all optimization regions, except for the ‘Ice’ region (Fig. S4), which was set to  $1 \times 10^{-8}$ . Emissions from ‘Ice’ region contribute only 0.02% of the global total emissions, and we did not expect the inversions to be able to optimize the emissions well. For  $L^{62}$ , an informative covariance matrix was used; the scaling factors for biospheric and anthropogenic emissions were assumed to be independent, and biospheric scaling factors were assumed to be correlated among mTCs based on the distance between the centres of the optimization regions (see *Supplementary Material* for further details). For  $L^{78}$ , a non-informative covariance matrix was used, i.e. all optimization regions were assumed to be independent.

## 2.2 TM5 chemistry transport model

The atmospheric chemistry transport model TM5 (Krol *et al.*, 2005) was used as an observation operator. TM5 was run with a  $1^\circ \times 1^\circ$  (latitude  $\times$  longitude) zoom region over Europe (24°N to 74°N, 21°W to 45°E), framed by an intermediate zoom region of  $2^\circ \times 3^\circ$ , and a global  $4^\circ \times 6^\circ$  degree resolution, driven by 3-hourly ECMWF ERA-Interim meteorological fields with 25 vertical layers. The atmospheric chemical loss, i.e. oxidation of  $CH_4$  initiated by reaction with OH, chlorine (Cl) and an electronically-excited state of oxygen ( $O(^1D)$ ), was pre-calculated based on Houweling *et al.* (2014) and Brühl and Crutzen (1993), and it was not adjusted in the optimization scheme. The atmospheric lifetime of  $CH_4$  estimated from the global total annual mean atmospheric chemical loss during 2000-2012 was about 9.7 years. Interannual variability was not applied in the removal rates of the  $CH_4$  sinks.

To establish reasonable initial conditions for the global distribution of CH<sub>4</sub> abundance, TM5 was run twice consecutively for 1999, starting from a uniform abundance of 1600 ppb globally using prior emission estimates. Using the final values, CTE-CH<sub>4</sub> was run for 2000, and the third run was used to define the initial CH<sub>4</sub> values at the beginning of 2000. Since atmospheric  
5 CH<sub>4</sub> concentrations did not increase significantly in 2000, it was assumed that this condition represents well-mixed initial atmospheric CH<sub>4</sub> for the experiments presented in this study.

In this study, two different convection schemes were used in TM5: Tiedtke (1989) (hereafter T1989) and Gregory *et al.* (2000) (hereafter G2000). The two versions differ mainly in vertical mixing in the troposphere: mixing is faster, and atmospheric CH<sub>4</sub>  
10 at the surface in the Northern Hemisphere (NH) is expected to be smaller with G2000 compared to T1989. Moreover, G2000 produces faster vertical mixing near the surface and also has a faster IH exchange time compared to T1989.

### 2.3 Prior CH<sub>4</sub> emissions

Five prior emission fields were used in this study and represented CH<sub>4</sub> release from anthropogenic, biospheric, fires, termites, and oceanic sources. Anthropogenic emissions accounted for about 60% of total global annual CH<sub>4</sub> emissions during 2000-  
15 2012. For prior anthropogenic emissions, the Emissions Database for Global Atmospheric Research version 4.2 FT2010 (EDGAR v4.2 FT2010) inventory was used. The original inventory data coverage extends to 2010; for 2011-2012, emission fields were assumed to be the same as 2010. Tuner *et al.* (2016) suggested that a large increase in anthropogenic emissions from the United States contributed significantly to the global growth in CH<sub>4</sub> emissions during 2002-2014. Although the 2010-2012 increase was not included in the prior, such increase are expected to be seen in the CTE-CH<sub>4</sub> after optimization. A  
20 seasonal cycle was not included in the EDGAR v4.2 FT2010 estimates. Emission estimates from the biogeochemistry model LPX-Bern v1.0 (Spahni *et al.*, 2013) were used as prior biospheric emissions, which accounted for about 30% of prior global total emissions. Emission estimates from rice fields were excluded from the prior biospheric emissions because they were already included in the prior anthropogenic emissions. In addition, consumption of CH<sub>4</sub> by methanotrophic bacteria in soils was estimated by LPX-Bern, and included as surface sinks in CTE-CH<sub>4</sub>. GFEDv3.1 (Randerson, 2014; van der Werf *et al.*,  
25 2010) was used for emission estimates from large scale biomass burning rather than the EDGARv4.2 FT2010 inventory. GFEDv3.1 emission estimates accounted for about 3% of prior global total emissions. The original data coverage is up to 2011, so the 2011 and 2012 emission fields were assumed to be unchanged from the last year available. However, global fire emissions in 2012 were about 2 Tg CH<sub>4</sub> yr<sup>-1</sup> larger than in 2011, mainly due to an increase in emissions in northwest Russia during the summer (GFEDv4.1; Giglio *et al.*, 2013). Therefore, we must be aware of an additional uncertainty in the spatial  
30 distribution of the emission sources, especially for 2012. Prior termite emissions are based on estimates from Ito and Inatomi (2012) for 2000-2006, which accounted for about 4% of prior global total emissions. The 2006 estimate was also used for 2007-2012. The estimates by Ito and Inatomi (2012) are about 10 Tg CH<sub>4</sub> yr<sup>-1</sup> smaller than the estimates reported by Sanderson

(1996) that were used in Bergamaschi *et al.* (2007), for example. Prior emission estimates from ‘natural’ open ocean were calculated assuming a supersaturation of CH<sub>4</sub> in the seawater of 1.3 (Lambert & Schmidt, 1993), which accounted for about 1% of prior global total emissions. ECMWF ERA-Interim sea surface temperature, sea ice concentration, surface pressure and wind speed (Dee *et al.*, 2011) were used to calculate the solubility and the transfer velocity (Bates *et al.*, 1966; Tsuruta *et al.*, 2015). No special treatment was applied to coastal emissions of the ‘natural’ ocean. In addition to the ‘natural’ ocean emission estimate, an ‘anthropogenic’ ocean emission estimate from EDGAR v4.2 FT2010 was added to the prior. Sources of anthropogenic ocean emissions are mainly from ships and other ‘non-road’ transportation. This includes emissions around coastlines. Prior fluxes from land and ocean anthropogenic sources, and from land biospheric sources, were optimized. Fluxes from fire, termites and natural ocean sources were not optimized.

## 10 **2.4 Atmospheric CH<sub>4</sub> observations**

Atmospheric observations of CH<sub>4</sub> abundance (reported in units of dry-air mole fraction) collected from the World Data Centre for Greenhouse Gases (WDCGG) were assimilated in CTE-CH<sub>4</sub>. The set of observations consisted of discrete air samples and continuous measurements from several cooperative networks (Table 2). The observations were filtered based on observation flags provided by each contributor to avoid the influence of strong local signals on the inversions. For continuous observations, daily means from selected hours were assimilated; afternoon observations (12:00-16:00 local time) were selected for most sites, but for the high altitude sites, night time observations (00:00-4:00 local time) were selected. These choices of sampling hours reflect a preference for well-mixed conditions that represent large source areas, and are also better captured by the TM5 transport model. Day-night selection was not applied to discrete observations. For each site, model-data-mismatches (mdm) were defined considering both the observation error and the transport model error, i.e. the ability of the transport model to simulate the observations. Note that the latter error is often much larger than the former. For the marine boundary layer (mbl) and the high latitude Southern Hemisphere sites (hLSH), mdm was set to 4.5 ppb. For sites that capture both land and ocean signals, mdm was set to 15 ppb. For sites that capture signals from the land, mdm was set to 25 ppb. For sites with a large variation in observations due to local influences, mdm was set to 30 ppb and for the sites that appeared problematic in the inversions, mdm was set to 75 ppb. Although the values of mdm are somewhat arbitrary, they are based on a previous study by Bruhwiler *et al.* (2014) and typically reflect the model forecast skill well. During assimilation, rejection thresholds were set as three times mdm, except for the mbl and hLSH sites. For these sites, rejection thresholds were set to 20 times mdm because assimilation of these observations is important in the characterization of the background atmospheric CH<sub>4</sub>. In this study, the observation covariance matrix was assumed diagonal, i.e. no temporal or spatial correlation between observations was taken into account.

## 30 **2.5 Aircraft profiles for evaluation**

Aircraft profiles of CH<sub>4</sub> abundance with altitude provide information about atmospheric CH<sub>4</sub> in general, but more specifically vertical transport. Aircraft data from regular profiling that operated within the European CarboEurope project at Orléans

(France), Bialystok (Poland), Hegyhatsal (Hungary) and Griffin (U.K.) during 2006-2012, which is a part of the European Union funded IA (Integrating Activity) project within the Integrated non-CO<sub>2</sub> Greenhouse gas Observation Systems (InGOS), were used for evaluation (Table 3). In addition, data from an aircraft campaign performed within the Infrastructure for Measurement of the European Carbon Cycle (IMECC) project were used. The IMECC campaign deployed a Learjet 35a with multiple vertical profiles from close to the surface up to 13 km near several TCCON sites in central Europe. For details on the airborne CH<sub>4</sub> measurements the reader is referred to Geibel *et al.* (2012). Aircraft observations were not assimilated in the inversions.

## 2.6 XCH<sub>4</sub> dataset for evaluation

In addition to the aircraft profiles and surface CH<sub>4</sub> measurements at in situ stations, column-averaged dry-air mole fractions (XCH<sub>4</sub>) from the TCCON network and the TANSO-FTS instrument on board the GOSAT spacecraft (Kuze *et al.*, 2009) were used for evaluation. XCH<sub>4</sub> data provided additional information in regard to long-range transport and helped to assess the quality of the global simulations. TCCON retrievals from the GGG2014 release (Wunch *et al.*, 2015) were used, and daily means were compared to simulated XCH<sub>4</sub> at each site. For GOSAT retrievals, the product reported by Yoshida *et al.* (2013) was used, and the regional daily mean for each mTC was compared to the corresponding simulation. The XCH<sub>4</sub> datasets were not assimilated in the inversions.

To facilitate a fair comparison, posterior XCH<sub>4</sub> were calculated using global 4°×6°×25 (latitude, longitude, vertical levels) daily 3-dimensional (3D) atmospheric CH<sub>4</sub> fields. For each retrieval, the global 3D daily mean gridded atmospheric CH<sub>4</sub> estimates were horizontally (latitude, longitude) interpolated to the location of the retrievals to create the vertical profile of simulated CH<sub>4</sub>. For comparison with GOSAT and TCCON retrievals, the retrieval specific averaging kernels (AK) were applied to model estimates based on Rodgers and Connor (2003):

$$\hat{C} = c_a + (\mathbf{h} \circ \mathbf{a})^T (\mathbf{x} - \mathbf{x}_a), \quad (4)$$

where  $\hat{C}$  is the quantity for comparison, i.e. XCH<sub>4</sub>.  $c_a$  (a scalar) is the prior XCH<sub>4</sub> of each retrieval,  $\mathbf{h}$  is a vertical summation vector,  $\mathbf{a}$  is an absorber-weighted averaging kernel of each retrieval,  $\mathbf{x}$  is a model profile, and  $\mathbf{x}_a$  is the prior profile of the retrieval. For the TCCON retrievals, one prior profile was provided each day, which was scaled to get the observed profiles that optimize the spectral fit (Wunch *et al.*, 2011). Prior profiles of GOSAT retrievals were provided for each retrieval (Yoshida *et al.*, 2013). Model estimated XCH<sub>4</sub> were calculated for each site for the comparison with TCCON XCH<sub>4</sub>, while the spatial mean of XCH<sub>4</sub> for each mTC was used for comparison with the GOSAT retrievals.

## 2.7 Inversion setups

In this study, three inversions were performed, which differed in number of parameters and TM5 convection schemes: (L<sup>62</sup>T) using L<sup>62</sup> configuration with the T1989 convection scheme, (L<sup>78</sup>T) using L<sup>78</sup> configuration with the T1989 convection scheme, and (L<sup>62</sup>G) using L<sup>62</sup> configuration with the G2000 convection scheme (Table 1). Prior and posterior CH<sub>4</sub> abundance was

estimated with TM5 using prior and posterior emission estimates, respectively. Posterior CH<sub>4</sub> was also estimated using the respective convection schemes in the forward runs.

### 3. Results

Before presenting and discussing the estimated CH<sub>4</sub> surface fluxes, agreements with the observations used in the assimilation (3.1) and with independent measurements from aircraft (3.2) and remote sensing products (3.3) are demonstrated.

#### 3.1 Atmospheric CH<sub>4</sub>

Atmospheric CH<sub>4</sub> values simulated using prior fluxes (prior atmospheric CH<sub>4</sub>) increases continuously during 2000-2012, and quickly exceeds observed atmospheric CH<sub>4</sub> levels, especially in the NH (Fig. 2, Fig. 3). The seasonal cycle of prior atmospheric CH<sub>4</sub> values agrees poorly with the observations with a positive bias from winter to summer in the NH compared to the observations, and around the end of each year in the Southern Hemisphere (SH) (Fig. 2). Furthermore, prior atmospheric CH<sub>4</sub> values are negatively biased compared to the observations in the SH around 2002-2004 (Fig. 2). This is likely due to an underestimation in the prior emissions in the SH. Posterior atmospheric CH<sub>4</sub> values generally match the observations to a level close to the expected model-data mismatch, indicating a proper choice of observation covariance. Seasonal bias remains in the NH (especially in L<sup>62</sup>T), and the decrease in atmospheric CH<sub>4</sub> in the SH around 2002-2004 also remains in the posterior, although shorter in duration and smaller magnitude than in the prior (Fig. 2). The negative bias in posterior atmospheric CH<sub>4</sub> around the equator remains unresolved throughout the study period in all inversions, and mainly originates from sites Bukit Koto Tabang, Indonesia (BKT) (-25 to -27 ppb) and Mt. Kenya, Kenya (MKN) (-18 to -23 ppb). The posterior atmospheric CH<sub>4</sub> values are especially low relative to observations during June-October. The bias became smaller when CH<sub>4</sub> emissions were increased in the South American tropical mTC region, although this led to compensating fluxes and mismatches with observations elsewhere (not shown). Posterior emissions for the South American tropical region (mTC3) remains similar to the prior, and the inversion does not significantly decrease the uncertainty of the prior emission estimates in this mTC (see Section 3.4.4 and 4.2).

Agreement between simulated CH<sub>4</sub> and surface observations is slightly better for L<sup>78</sup>T and L<sup>62</sup>G than for L<sup>62</sup>T (Fig. 2) as indicated by the root mean squared error (RMSE), which is about 0.5 ppb smaller. In addition, the biases in annual amplitude are about 1-2 ppb smaller. The negative bias in the SH from 2002 to 2004 is seen in all inversions, but is most prominent in L<sup>62</sup>T. Although the difference in the average RMSE is small, it is significant as it is calculated from all the observations assimilated in the study period. In addition, differences are significant when the ensemble distributions of posterior atmospheric CH<sub>4</sub> are considered. The spread (1 standard deviation=std) of ensembles are less than 5 ppb for most sites and less than 1 ppb for mbl sites, mostly located in the SH.

Further evidence for poorer performance of L<sup>62</sup>T than other runs is seen in its global fluxes. L<sup>62</sup>T produced the smallest total global emission estimates for 2002-2004, which in turn led to the largest increase in the total global emission estimates from 2001-2006 to 2007-2012. Based on previous studies (e.g. Bergamaschi *et al.* (2013), Bousquet *et al.* (2006), Bruhwiler *et al.* (2014) and Fraser *et al.* (2013)), the increase in L<sup>78</sup>T and L<sup>62</sup>G are more reasonable (see Section 3.4.1). The differences in RMSE and bias between the latter inversion estimates are small near 30°N, where many observations are located. However, the RMSE and bias in L<sup>78</sup>T are about 1 ppb and 2 ppb smaller at high northern latitudes (60°N-75°N), and about 3 ppb and 6 ppb larger around the equator (EQ-15°N) than in L<sup>62</sup>G, respectively. Moreover, low atmospheric CH<sub>4</sub> values in the SH during 2002-2004 are not as prominent in the prior when the G2000 convection scheme is used (Fig. 2), probably due to enhanced transport between the NH and SH in L<sup>62</sup>G. Mean Chi-squared statistics (Michalak *et al.*, 2005) of the observations are typically between 0 and 2, and follow normal distributions (not shown), which again indicates that the mdm estimates are appropriate at most of the sites.

In contrast to the prior, the growth rate (GR) of posterior XCH<sub>4</sub> does not change strongly before 2007, but increases after 2007 (Fig. 3). All inversions show an increase in XCH<sub>4</sub> by about 6 ppb yr<sup>-1</sup> after 2007, with some seasonal and interannual variations (Fig. 3). The timing of the change in posterior XCH<sub>4</sub> GR is in line with the GR calculated from the global network of NOAA mbl observations (Dlugokencky *et al.*, 2011) and with the retrieved XH<sub>4</sub> GR at Park Falls (Fig. 3). This indicates that the GR of prior XCH<sub>4</sub> is too large throughout 2000-2012 (see also Fig. 2), and this can only result from overestimated emissions or underestimated loss of CH<sub>4</sub>. Note that the NOAA mbl observations compared in Fig. 3 are calculated from surface observations.

### 20 3.2 Evaluation with aircraft measurements

Posterior atmospheric CH<sub>4</sub> generally agrees well with independent vertical profiles from aircraft. The average RMSE decreased from 80 ppb in the prior to 24 ppb in the posterior (Fig. 4, Table 3). The RMSE between posterior and observed atmospheric CH<sub>4</sub> values is smallest for GRI (<12.9 ppb), and largest for Orléans, France (ORL) (>37.4 ppb) (Fig. 4). The model performance at in situ sites near Griffin, UK (GRI) is good, i.e. the correlations between assimilated observations and posteriors are high, and the RMSE is equal to or smaller than the mdm (Fig. 5). This suggests that emission estimates are well constrained, at least in the NH, although the RMSE is much larger than those at surface sites due to vertical transport. The model performance at in situ sites near ORL is poor, and the bias in the ORL profiles extends up to 2 km, which was also seen in Bergamaschi *et al.* (2015). The comparison with IMECC observations from central Europe shows the effect of the convection scheme on the profiles above 2 km. Negative biases are seen in the inversion estimates using the T1989 scheme from 2-10 km. The bias in the inversion estimates using the G2000 scheme is small at around 2-10 km, but is positive in the upper troposphere and lower stratosphere, where the estimates using T1989 better match the observations. This could however be due to diffusive

transport near the tropopause simulated by the 25 vertical layers in TM5. The use of a higher vertical resolution of TM5 might improve the agreement with observations at higher altitudes for both convection schemes.

### 3.3 Evaluation with TCCON and GOSAT XCH<sub>4</sub>

XCH<sub>4</sub> provided additional information about the spatial distribution of atmospheric CH<sub>4</sub>. TCCON and GOSAT XCH<sub>4</sub> retrievals were not assimilated in the inversions, so the following comparisons also allow an assessment of model performance at independent locations and times.

For many TCCON sites in the NH, L<sup>62</sup>T and L<sup>78</sup>T XCH<sub>4</sub> are slightly lower than observed, but the trend and seasonal variability are generally well captured. However, the 2007-2012 trends at Izaña (Spain), Park Falls (U.S.A.) and Lamont (U.S.A.) are much stronger than in the retrievals (Fig. 6). Since the emission estimates at similar latitudes would affect the XCH<sub>4</sub> estimates, this could be an effect of the strongly increasing northern temperate emission estimates after 2007 (Section 3.4.2). The RMSE between the estimates and retrievals are smallest in L<sup>62</sup>G at all sites, except at Garmisch, Germany (Table 4). Garmisch is a mountain site (altitude 734 m a.s.l.), and the mean of observed XCH<sub>4</sub> is statistically significantly lower than at near-by sites, e.g. Karlsruhe, Germany, and Bialystok, Poland (Fig. 6, Fig. S5).

For the SH TCCON sites, a strong negative bias is found in all inversions (Fig. 6, Fig. S5). Agreement is especially poor for Wollongong, with the largest RMSE (more than 30 ppb) among all TCCON sites in all inversions (Table 4). As the site is located in the city of Wollongong, where the influence of local emissions is high, it is difficult for models to reproduce XCH<sub>4</sub> well (Fraser *et al.*, 2013). The comparison with the nearest in situ site, Cape Grim, Australia (CGO) show that the negative bias is much smaller (-6 to -11 ppb), and the correlation with the retrievals is high (>0.85). In addition, the negative bias in XCH<sub>4</sub> is much smaller (-12 to -15 ppb) at background site Lauder, New Zealand (LAU) and the correlation at LAU in situ site is again strong (>0.85) in all inversions. The disagreement at Darwin is probably due to little constraint of the emissions. Although in situ observations at Gunn Point, Australia (GPA) were assimilated, the inversion probably did not benefit significantly from these observations because data were available only after mid-2010, and the mdm was set high (75 ppb). Furthermore, emissions from the tropics also affect the XCH<sub>4</sub> estimates in Australia. Our emission estimates for the tropics (30°S-30°N) are about 10-20 Tg CH<sub>4</sub> yr<sup>-1</sup> smaller than the estimates by Houweling *et al.* (2014), for example. When the prior emission estimates for the South American tropical region (mostly between 15°S-15°N) are increased (see Section 3.1), agreement in the SH improved (not shown). The comparison with GOSAT XCH<sub>4</sub> also support the finding from the comparison with the TCCON retrievals, showing a mean negative bias of 13 ppb in the SH (Fig. S6). We currently do not have sufficient information to correct the errors that affected the SH XCH<sub>4</sub> in our system, nor identify the exact cause.

Spring peaks seen in GOSAT XCH<sub>4</sub> in global, ocean and the Asian tropical mTC region points to an important role of the vertical mixing scheme, which are well captured in L<sup>62</sup>G, but not in L<sup>62</sup>T and L<sup>78</sup>T (Fig. 7, Fig. S6). The difference is

statistically significant considering the ensemble distribution. Monthly emission estimates in L<sup>62</sup>G are generally larger than in L<sup>62</sup>T and L<sup>78</sup>T during November-April, especially in the northern latitude temperate regions (35°N-60°N, Fig. S7). This suggests that winter emissions in the northern latitude temperate regions, enhanced in the model by faster vertical mixing around the surface, play an important role to reproduce the XCH<sub>4</sub> seasonal cycle in the tropics well.

5

Although GOSAT retrievals are valuable for evaluating model performance, it is important to keep in mind that the satellite retrievals do not always agree with ground-based TCCON retrievals. GOSAT XCH<sub>4</sub> has been evaluated against TCCON retrievals, but biases in the GOSAT products remain, especially in the latitudinal gradient (Yoshida *et al.*, 2013). This is probably one of the reasons for the positive model bias in the NH compared to GOSAT (Fig. S6). Furthermore, the seasonal amplitude of GOSAT XCH<sub>4</sub> is much smaller than that of the posterior estimates, especially in the SH (Fig. S6). This is not in line with the TCCON comparison (Fig. 6, Fig. S5), which suggest that disagreement with GOSAT XCH<sub>4</sub> in the latitudinal gradient and the seasonal amplitude may not be only due to problems in the inversions.

10

### 3.4 Emission estimates

#### 3.4.1 Global

15

Our posterior mean total global emissions estimate for 2000-2012 is 517±45 Tg CH<sub>4</sub> yr<sup>-1</sup> with an increasing trend of 3 Tg CH<sub>4</sub> yr<sup>-1</sup> (Table 6, inversion L<sup>62</sup>G). Posterior mean total global emissions for 2000-2012 are approximately 29 Tg CH<sub>4</sub> yr<sup>-1</sup> smaller than the prior (Table 6), although the posterior estimates are within the range of prior uncertainties (±93 Tg CH<sub>4</sub> yr<sup>-1</sup>). Posterior mean total global emission estimates from inversions L<sup>62</sup>T, L<sup>78</sup>T and L<sup>62</sup>G agree well, and are in line with previous studies, e.g. Bousquet *et al.* (2006) and Fraser *et al.* (2013). The main differences in the long-term mean is that anthropogenic mean annual emission estimates in L<sup>78</sup>T are more than 10 Tg CH<sub>4</sub> yr<sup>-1</sup> larger than L<sup>62</sup>T and L<sup>62</sup>G, which are compensated by smaller biospheric emissions (Fig. 8). This change in long-term mean flux is not robust in the L<sup>78</sup> configuration, as the uncertainty is large.

20

All inversions show an increase in posterior mean total global emissions from before 2007 to after 2007 by 18-19 Tg CH<sub>4</sub> yr<sup>-1</sup> (Table 6), which is much smaller than the increase in prior emissions of 33 Tg CH<sub>4</sub> yr<sup>-1</sup>. The increase in posterior emissions during 2000-2010 is 15-16 Tg CH<sub>4</sub> yr<sup>-1</sup> and this agrees well with previous studies by Bergamaschi *et al.* (2013) and Bruhwiler *et al.* (2014) for example, who estimated an increase of about 16-20 Tg CH<sub>4</sub> yr<sup>-1</sup>.

25

The increase in total global emissions is dominated by the anthropogenic sources in both posterior and prior, and again the increase in the posterior (15-28 Tg CH<sub>4</sub> yr<sup>-1</sup>) is much less than in the prior EDGAR v4.2 FT2010 inventory (37 Tg CH<sub>4</sub> yr<sup>-1</sup>) (Fig. 9, Table 6). The posterior anthropogenic emission estimates from 2003-2005 to 2007-2010 increase by 15-23 Tg CH<sub>4</sub> yr<sup>-1</sup>, which agrees well with Bergamaschi *et al.* (2013) who estimated the increase at 14-22 Tg CH<sub>4</sub> yr<sup>-1</sup>. However, the increase

30

in anthropogenic emission estimates is larger than reported by Bruhwiler *et al.* (2014) who found an increase of around 10 Tg CH<sub>4</sub> yr<sup>-1</sup> from 2000-2005 to 2007-2010. The differences between the inversions are partly due to different time periods used, but also due to the use of different sets of observations and prior fluxes. Bergamaschi *et al.* (2013) used SCIAMACHY satellite-based retrievals and NOAA observations, whereas Bruhwiler *et al.* (2014) used in situ NOAA discrete and Environmental Canada (EC) continuous observations. Our study is also based on in situ observations, but include more discrete and continuous observations globally than the previous two studies. Therefore, estimates from our study could potentially contain important additional information from observations other than those from NOAA and EC. In regard to prior emissions, this study and Bergamaschi *et al.* (2013) used EDGAR v4.2 inventory estimates (the estimates are similar although slightly different versions were used), while Bruhwiler *et al.* (2014) used a constant prior from EDGAR v4.2 for 2000. Although Bergamaschi *et al.* (2013) found a significant increase in anthropogenic emissions in the constant-prior inversion, the increase was slightly smaller than in their inversions with the trend included in the prior. This could have caused the smaller trend estimated by Bruhwiler *et al.* (2014), compared to this study.

Biospheric emission estimates in the L<sup>62</sup>T and L<sup>62</sup>G inversions after 2007 are slightly smaller than before 2007 (-5 to -2 Tg CH<sub>4</sub> yr<sup>-1</sup>), following the prior (-1 Tg CH<sub>4</sub> yr<sup>-1</sup>). In contrast, L<sup>78</sup>T shows an increase (+7 Tg CH<sub>4</sub> yr<sup>-1</sup>). The increase is driven by much smaller biospheric emission estimates in the L<sup>78</sup>T inversion before 2007, mainly due to significantly smaller biospheric emissions in the temperate Asian region (discussed in Section 3.4.3). The small negative trend in biospheric emissions in L<sup>62</sup>T and L<sup>62</sup>G is in line with the finding by Bergamaschi *et al.* (2013). Here, it is again important to note that interannual variability in the CH<sub>4</sub> sink, which could also influence total emissions to the atmosphere, is not included in this study.

### 3.4.2 Northern Hemisphere boreal regions and Europe

In this section, results for the following mTCs are presented: North American boreal region (mTC1), Eurasian boreal region (mTC7), and Europe (mTC11-14).

Posterior anthropogenic emissions for Europe as a whole (mTC11-14) are similar to the prior (L<sup>62</sup>T, L<sup>78</sup>T) (Table 6), but shifts in the relative contributions to total European emissions from different parts of Europe occurred. Posterior emissions are larger than the prior in southern Europe (south-west Europe (mTC11) and south-east Europe (mTC12), whereas the posterior is smaller than the prior in north-east Europe (mTC14) in all inversions (Table S1). Most of the increase in southern Europe and the reduction in north-east Europe are due to anthropogenic emissions. Observed atmospheric CH<sub>4</sub> during winter at many of the in situ sites in northern Europe can be good indicators of anthropogenic signals, because emissions from biogenic sources are small during winter. Posterior atmospheric CH<sub>4</sub> at these sites during winter agrees well with observations, which would indicate that the posterior anthropogenic emissions are reasonable. Southern Europe is only a small source of biospheric emissions, so most of the atmospheric signals captured at the in situ sites in the region are from anthropogenic sources. In southern Europe, posterior atmospheric CH<sub>4</sub> values at some sites in France, Spain and Italy have a strong positive bias (> 10

ppb), which exceed the ensemble standard deviations, although the correlations between observed and posterior CH<sub>4</sub> are strong (0.8 or larger). The posterior atmospheric CH<sub>4</sub> values at other sites in south-east Europe are not overestimated, but the correlations are often weaker. This suggests that the inversion did not find a solution that matches all the observations equally, because of an incorrect distribution in the prior within the optimization region. It could also imply that some measurements had local influence that the model could not represent or that the mdm was too small for a few sites. However, the Chi-squared statistics at European sites showed no indication that mdm was too small. Evaluation with aircraft observations shows that vertical transport of CH<sub>4</sub> in Europe is generally good, but evaluation data were only available from central Europe, i.e. we cannot exclude the problem of mixing in the atmosphere elsewhere. Posterior anthropogenic emissions for north-west Europe are similar to the prior. This finding is in line with Bergamaschi *et al.* (2015), who estimated the anthropogenic emissions in north-west European countries to be similar to the EDGARv4.2 estimates and larger than the emissions reported in UNFCCC (2013).

For biospheric emission estimates, differences between prior and posterior emissions are negligible in southern Europe (Table S1), whereas the reduction in the posterior is clear in northern Europe (north-west and north-east Europe) (Fig. S8). A reduction in biospheric emission estimates is also estimated for the North American boreal region (Fig. S8). This suggests that the prior biospheric emissions in boreal regions are too large, which results in larger prior atmospheric CH<sub>4</sub> values than observed. The interannual variability in the posterior emissions also does not follow the prior. An increase in the posterior biospheric emissions is found for 50°N-90°N in 2006, followed by a decrease until 2010, which is not prominent in the prior. Most of the 2006 increase is from the North American boreal region. This finding does not agree with previous studies, e.g. Bousquet *et al.* (2011), who found little increase in high northern latitude wetland emissions in 2006. Instead, a significant increase in emissions was found in 2007 in their study. However, observations from a specific locations support our findings, although the representativeness of a regional scale signal is questionable. Moore *et al.* (2011) reported that 2006 was a warm and wet year at Mer Bleue bog in Canada (45.41°N, 75.48°W), and for the period 2004-2008, the highest autumn CH<sub>4</sub> emissions were observed in 2006. The posterior biospheric emission estimates for north-east Europe in 2006 are about 60% smaller than the prior estimate in all inversions. Drewer *et al.* (2010) found that CH<sub>4</sub> emissions in September in Lompolojännkä fen in Finland (67.60°N, 24.12°E) were larger in 2006 than in 2007 due to heavy rain. However, the summer of 2006 was dry with low emissions and snow had already started to fall by the end of September, cutting the emission season short with below zero (°C) temperatures. As such, mean annual CH<sub>4</sub> emissions from the fen were lower in 2006 than in 2007. The high prior emission in September-October 2006 could be due to a bias in precipitation (excluding snow) and temperature in meteorological data from Climatic Research Unit (CRU), University of East Anglia, UK (Mitchell and Jones, 2005), which was used as an input for the LPX-Bern model. CRU precipitation and temperature at Lompolojännkä and the mTC14 average are larger than in the observations at Lompolojännkä during autumn 2006. The posterior summer biospheric emissions in 2007 are nearly twice as large as the prior. The posterior shows high emissions in July, but the LPX-Bern estimates are low during the summer and autumn at Lompolojännkä and in mTC14 on average. This could be due to problems in the wetland fraction or in the

precipitation dependence. CRU precipitation in 2007 is high in early summer and extremely heavy in July at Lompolojänkkä and in mTC14 on average, which is in line with Drewer *et al.* (2010). Although the seasonal cycle of the precipitation is well captured in CRU, if the peatland soil is already saturated with water in early summer, CH<sub>4</sub> emissions would not have increased with additional high summer precipitation. For north-west Europe, similar results are found; posterior biospheric emissions are low in summer-autumn 2006 and high in summer 2007 compared to the prior. The CRU meteorology again agrees well with measurements at Stordalen mire in northern Sweden (68.20°N, 19.03°E) for example, where the measured emissions (Jackowicz-Korczyński *et al.*, 2010) also support the posterior estimates more than the prior.

Differences in emissions between the T1989 and the G2000 convection schemes are prominent in all northern boreal regions and Europe. Posterior emissions in L<sup>62</sup>G are larger than in L<sup>62</sup>T and L<sup>78</sup>T throughout 2000-2012. The estimated prior surface atmospheric CH<sub>4</sub> values in these regions are lower when the G2000 scheme is used. This indicates that the stronger vertical transport in the G2000 reduces the surface CH<sub>4</sub> abundance faster than the T1989 scheme and lead to larger posterior emissions. We cannot conclude which convection scheme is more suitable for northern boreal regions and Europe based only on the posterior atmospheric CH<sub>4</sub> of those regions, but the agreement with the model independent aircraft and TCCON retrievals are better in the inversion using the G2000 scheme than others using the T1989 scheme. This supports van der Veen *et al.* (2013) who found that G2000 more accurately represented vertical transport by simulating atmospheric SF<sub>6</sub>. Note that the number of available GOSAT retrievals, which agree better with the inversion results using T1989 scheme, is limited for northern Europe, and the retrieval bias (Yoshida *et al.*, 2013) makes the independent information less reliable.

### 3.4.3 Northern Hemisphere temperate regions

In this section, results for North American (mTC2) and Asian (mTC8) temperate regions are presented.

Posterior total emissions for the North American temperate region are larger than prior emissions in all inversions (Fig. S8, Table 6). The main contribution to the increase in total regional emissions is anthropogenic emissions. Posterior mean anthropogenic emissions for 2000-2001 are closer to the prior, but nearly 10 Tg CH<sub>4</sub> yr<sup>-1</sup> larger than the prior for 2004-2012 (Fig. S8). The trend during 2000-2012 is not significant in the prior or in the posterior, although the posterior shows an increase of 0.5 Tg CH<sub>4</sub> yr<sup>-1</sup> during 2000-2012. The estimated growth rate is similar to the estimates reported by Bruhwiler *et al.* (2014), but only about one third of that reported by Turner *et al.* (2016). Our evaluation shows that the trend in posterior XCH<sub>4</sub> matches well the GOSAT and TCCON retrievals regionally and at sites in the USA, e.g. Park Falls and Oklahoma (Fig. 6, Fig. S5, Fig. S6). In this study, emissions were optimized region-wise, and there was only one scaling factor for anthropogenic emission estimates for the North American temperate region. Therefore, it is not possible to study the differences in the emissions trend on the eastern and western sides of the North American temperate region, as in Turner *et al.* (2016). However, this study suggests that a large increase in local emissions is not necessary to reproduce the increasing atmospheric CH<sub>4</sub> trend. Long-range transport plays a more important role than the local emissions.

A negative correlation is found between mean posterior anthropogenic and biospheric emissions for the North American temperate region, i.e. anthropogenic emissions increased when biospheric emissions decreased. This is an effect of the inversion not being able to separate biospheric and anthropogenic emissions based on the current observational network. In situ observation sites in this area are mostly close to anthropogenic emission sources, so the interannual variability found in biospheric emission estimates may not represent the real variability.

The Asian temperate region has large anthropogenic and biospheric emissions (Table 6). Anthropogenic emissions are responsible for most of the increase in the prior regional and total global emission estimates after 2007. However, prior anthropogenic emissions in this mTC are reduced by more than half in the posterior (Fig. 8, Table 6). Moreover, the increase in posterior anthropogenic emissions for 2000-2012 is not as strong as in the prior (Fig. 8, Table 6). The significant reduction in anthropogenic emissions from prior to posterior estimates for 2002-2010 is driven by observations from two continental sites in Korea; Anmyeon-do (AMY, data available for 2000-2012) and Gosan (GSN, data available for 2002-2011). Small values of mdm were initially assigned and thus the sites had a large impact on the regional flux estimates. When mdms for those sites are set to 1000 ppb, thereby reducing their influence in the inversion (referred to as L<sup>62</sup>T-K, L<sup>78</sup>G-K), the estimated total emission in this mTC is about 30 Tg CH<sub>4</sub> yr<sup>-1</sup> larger and in better agreement with Bruhwiler *et al.* (2014) and Bergamaschi *et al.* (2013) for example.

The increased Asian temperate emissions in simulations L<sup>62</sup>T-K and L<sup>78</sup>G-K are mainly compensated by reduced fluxes in the Asian tropical region (about 10 Tg CH<sub>4</sub> yr<sup>-1</sup> in L<sup>62</sup>, about 20-30 Tg CH<sub>4</sub> yr<sup>-1</sup> in L<sup>78</sup>) (Fig. 8), as well as in the Eurasian boreal region, Europe, and the ocean. Only small changes are found in regional emission trends, but the anthropogenic ocean emission estimates in L<sup>62</sup>T-K and L<sup>78</sup>G-K increase less during 2009-2012 compared to that in L<sup>62</sup>T and L<sup>78</sup>T. When the two Korean sites are excluded from the inversion, the posterior biospheric emissions in the Asian temperate region remain close to the prior. The interannual variability in total emissions in L<sup>62</sup>T-K and L<sup>78</sup>G-K is smaller than that of L<sup>62</sup>T and L<sup>78</sup>G for the Asian temperate region. It is rather unrealistic that regional anthropogenic emissions change by more than 30 Tg CH<sub>4</sub> yr<sup>-1</sup> over one to two years as is the case in L<sup>62</sup>T, L<sup>78</sup>T, and L<sup>62</sup>G. Fast growing economies, such as China and India are located in the Asian temperate region, and there is no evidence that the anthropogenic emissions decreased significantly during 2002-2010 in that region. Total emission estimates for the Asian temperate region in L<sup>62</sup>T-K and L<sup>78</sup>G-K are larger and more reasonable than in L<sup>62</sup>T and L<sup>78</sup>T, and the ratio of anthropogenic to biospheric emission estimates in L<sup>62</sup>T-K and L<sup>78</sup>G-K are more consistent with each other than in L<sup>62</sup>T and L<sup>78</sup>T. This suggests that the L<sup>62</sup>T and L<sup>78</sup>T posterior anthropogenic emissions and the L<sup>78</sup>T posterior biospheric emissions for 2002-2010 are probably unreasonably low due to the influence of the two Asian sites, AMY and GSN. Nevertheless, the posterior emissions in L<sup>62</sup>T and L<sup>78</sup>T are lower than in the EDGAR v4.2 FT2010, which is in agreement with previous studies (Pandy *et al.*, 2016; Thompson *et al.*, 2015). The effect of the changes in the emission estimates (L<sup>62</sup>T-K and L<sup>78</sup>G-K) to XCH<sub>4</sub> is small, although a slight increase is found globally. The agreements with GOSAT and TCCON

XCH<sub>4</sub> in L<sup>62</sup>T-K and L<sup>78</sup>G-K are slightly better for mTCs and at sites where negative biases are found in L<sup>62</sup>T and L<sup>78</sup>T (not shown).

#### 3.4.4 Asian and South American tropical regions

In this section, results for the following regions are presented: South American tropical (mTC3) and Asian tropical (mTC9).

5

The Asian tropical region also has large anthropogenic and biospheric emissions. Prior estimates from both sources are about 30 Tg CH<sub>4</sub> yr<sup>-1</sup> each, and they are reduced slightly by the inversions (Fig. 8, Table 6). Posterior estimates for biospheric and anthropogenic emissions are lower than in Bruhwiler *et al.* (2014), who estimated the anthropogenic emissions to be even larger than, and biospheric emissions to be similar to, our prior. The L<sup>78</sup>T anthropogenic emission estimates are lower than the prior estimates due to enhanced, and probably unrealistic, interannual variability compared to the L<sup>62</sup>T and L<sup>62</sup>G estimates (Fig. 8). This partly correlates with the strong interannual variability in the Asian temperate region. For example, the increase in anthropogenic emissions in L<sup>78</sup>T around 2002-2005 is due to a strong decrease in emissions in the Asian temperate region. In the test cases, L<sup>62</sup>T-K and L<sup>78</sup>G-K, interannual variability in both the Asian temperate and Asian tropical regions is smaller than in L<sup>62</sup>T and L<sup>78</sup>T (Fig. 8). However, annual anthropogenic emission estimates in L<sup>78</sup>G-K are much lower than in L<sup>78</sup>T, and about 20 Tg CH<sub>4</sub> yr<sup>-1</sup> smaller than in L<sup>62</sup>G. This is partly due to the differences in the convection schemes, which is also seen in the L<sup>62</sup> configuration. However, it is mostly due to compensating effect of the increased Asian temperate anthropogenic emissions that resulted from reducing influence of the observations at the Korean sites. Evaluation with surface in situ observations shows that L<sup>62</sup>G atmospheric CH<sub>4</sub> values agree best with observations at BKT, where the inversions have a strong negative bias. Nevertheless, large uncertainty remains in the estimates, so further information, such as additional observations and prior information about the emissions, is needed to better quantify emissions in this region.

20

The emission estimates for the South American tropical region are very similar to each other (Fig. S8, Table S1). All posterior emissions are close to the prior, and the uncertainty in the posterior is not reduced by the inversions. This is due to a lack of observations assimilated within the optimization regions in mTC3. Three stations (MEX, KEY, RPB) near the edge of mTC3 were assimilated, but due to strong vertical transport, these observations does not capture signals from tropical wetlands, which is the main CH<sub>4</sub> source from this mTC. Moreover, most of the assimilated observations are samples from well-mixed air mass that represented a large volumes of the atmosphere. Therefore, the inversions could not satisfactorily constrain emissions in the South American tropical region.

25

#### 3.4.5 Africa and southern mid-latitudes

In this section, results for the following regions are presented: South American temperate region (mTC4), northern Africa (mTC5), southern Africa (mTC6) and Australia (mTC10).

30

Posterior total emissions in the South American temperate region increase significantly during 2006-2009 in all inversions (Fig. S8), and there is no correspondent decrease in other mTCs, e.g. the Asian temperate region. All inversions point in the same direction, but the results are still debatable. Observations assimilated within mTC4 before 2006 are from Ushuaia (USH) in Argentina. Due to its location (54.85°S) having few local emission sources, the purpose of the sites is to sample well-mixed  
5 air that represents large volumes of the atmosphere. Observations at Arembepe, Brazil (ABP) were available during 2006-2009, and at Natal, Brazil (NAT) during 2010-2012. These sites capture the well-mixed air in the tropics better than USH, although most of the signals are from the Atlantic Ocean and not from the land. Interannual variability in the tropics is probably better represented by ABP and NAT observations, but it is questionable whether the variability is driven by the observation signals from the South American temperate region. Similar interannual variability was reported by Bruhwiler *et al.* (2014),  
10 where ABP observations were assimilated (the NAT observations were outside their study period), although the changes were not as significant as in this study.

South American temperate is the only region where all inversions show a significant increase in both anthropogenic and biospheric emissions (Table 6). As mTC4 is mostly within 30°S-30°N, and most of the emissions are located in the northern  
15 part of this mTC, the estimates agree with Houweling *et al.* (2014) who found that most of the increase in total global emissions was in the tropics and the extratropics. The increase in emissions during 2005-2008 and the subsequent decrease (Fig. S8) was also found in Basso *et al.* (2016), who suggested that biospheric emissions from the east part of the Amazon basin were the main contributor to interannual variability. Dlugokencky *et al.* (2011), using constraints from CH<sub>4</sub> isotopic measurements, suggested emissions from the tropics were an important contributor to the significant growth in atmospheric CH<sub>4</sub> after 2007.  
20 The isotopic measurements showed a decrease in the  $\delta^{13}\text{C-CH}_4$ , which would indicate that the increased emissions were probably from biogenic sources. The inversions in this study have difficulty changing the ratio of anthropogenic to biospheric emissions from the prior, which could be a reason why the interannual variability of total emissions is optimized by changing emissions from the major sources, i.e. anthropogenic. Therefore, interannual variability of the posterior emissions is dominated by the contributions from anthropogenic sources.

25  
Posterior anthropogenic emissions in the northern Africa and southern Africa mTCs are larger than the prior for all inversions, with somewhat different interannual variability in the north and south (Fig. S8). Evaluation with in situ observations in northern Africa shows that there is only a small bias in the posterior atmospheric CH<sub>4</sub> values (<1 ppb in L<sup>62</sup>G). For southern Africa, agreement with the in situ observations is good, except for Mt. Kenya, Kenya (MKN) where a strong negative bias is found  
30 (see Section 3.1). The correlation between the posterior and observed atmospheric CH<sub>4</sub> values at MKN is strong ( $\geq 0.8$ ), and the site is located at a high altitude (>3000 m a.s.l.), which implies that the bias may not be due to small local emissions. On the other hand, vertical transport in the tropics is strong, and MKN is located near a biospheric source area in central Africa. Therefore, the negative bias could also be due to an underestimation of emissions from wetlands in central Africa. Bruhwiler *et al.* (2014) also reported an increase in the posterior estimates compared to their prior in Africa, but the increase was mainly

in biospheric emissions. However, our interannual variability in anthropogenic emissions in northern Africa is similar to their variability in central African biospheric emission estimates. Therefore, the differences may partly be due to differences in the prior: the ratios of prior anthropogenic to biospheric emissions in this study and Bruhwiler *et al.* (2014) are almost reciprocals of each other, i.e. our prior anthropogenic emissions are larger and biospheric emissions are lower than in Bruhwiler *et al.* (2014). It is not possible to conclude from this study which estimates better capture actual emissions, because the estimates for Africa are not well constrained by the observations in either study.

Posterior emissions for Australia in L<sup>78</sup>T re systematically larger than in L<sup>62</sup>T and L<sup>62</sup>G throughout 2000-2012 (Fig. S8). The southern-most coast of Australia and much of New Zealand is defined as ‘biospheric’ land in L<sup>62</sup> configuration (Fig. S4), i.e. anthropogenic emissions in that optimization region are not optimized in L<sup>62</sup>T and L<sup>62</sup>G. Since biospheric emissions are a minor source and the posterior emissions change little from the prior in L<sup>78</sup>T, the ‘biospheric’ land in the land-ecosystem map may need to be changed to ‘anthropogenic’ land for mTC10 to be able to optimize anthropogenic emissions better in L<sup>62</sup>T and L<sup>62</sup>G.

### 3.4.6 Ocean

Prior anthropogenic ocean emissions are mainly in the tropics (mTC20), and the main differences between prior and posterior emissions are also located in this mTC (Fig. S9). All posterior fluxes are 5-10 Tg CH<sub>4</sub> yr<sup>-1</sup> larger than the prior, especially before 2006 and during 2011-2012 (Fig. S9). However, it is questionable whether these results are reasonable, since there is no indication that non-road transportation and coastal anthropogenic emissions estimates varied from year-to-year as the inversion results show. It is more likely that ocean regions are used to compensate for missing tropical land emissions. Indeed, the estimates for the ocean were sensitive to the estimates in other regions (not shown). Further investigation without optimizing anthropogenic ocean emissions or using only natural ocean emissions as prior, i.e. excluding non-road transport (ship and aircraft) emissions, would help us to better understand the anthropogenic emission estimates over land. Note that the prior biospheric emission estimates in mTC16-20 were not optimized. Prior biospheric emissions around the coast were not zero, partly due to differences in the definition of the coast in the mTC16-20 line in our mTC map and the prior. Only limited information is available in regard to biospheric emissions around coastlines, and as it is a minor source, it was assumed that the inversion would not be able to optimize it.

## 4. Discussion

### 4.1 Differences between inversions

Interannual variability of emission estimates is often stronger in L<sup>78</sup>T than in L<sup>62</sup>T and L<sup>62</sup>G. Differences are mainly seen in the Asian temperate region, where the proportion of biospheric emissions to total emissions is much smaller in L<sup>78</sup>T than in

L<sup>62</sup>T and L<sup>62</sup>G. Anthropogenic emission estimates for the Asian tropical region in L<sup>78</sup>T show strong interannual variability, although the biospheric emission estimates in L<sup>78</sup>T are similar to the L<sup>62</sup>T and L<sup>62</sup>G estimates. The ratio of biospheric to anthropogenic emission estimates in the Asian temperate and Asian tropical regions changes from year to year in L<sup>78</sup>T. The dominant sources are similar in L<sup>62</sup>T and L<sup>62</sup>G, but sometimes different in L<sup>78</sup>T. For example, in the Asian temperate region, biospheric emissions are larger than anthropogenic emissions during 2003-2005 in L<sup>62</sup>T and L<sup>62</sup>G, but lower in L<sup>78</sup>T. Only small differences are found in the posterior values of XCH<sub>4</sub> in L<sup>62</sup>T and L<sup>78</sup>T. Agreement with in situ CH<sub>4</sub> observations is better in L<sup>78</sup>T than in L<sup>62</sup>T, i.e. the negative bias in the SH is less pronounced in L<sup>78</sup>T. The emission estimates in the SH are often larger in L<sup>78</sup>T than in L<sup>62</sup>T, where differences are mainly seen in the anthropogenic emission estimates. This means that the land-ecosystem distribution used in this study generally represents the division of the source areas well, although some revision may be needed for Asia and the SH, e.g. Australia.

As expected, interannual variability of emissions in L<sup>62</sup>T and L<sup>62</sup>G are similar. This shows that the different convection schemes does not have a large effect on the interannual variability of the emission estimates in L<sup>62</sup> configuration. The north-south gradient of emissions shows that NH emissions are about 10 Tg CH<sub>4</sub> yr<sup>-1</sup> larger, and SH emissions about 10 Tg CH<sub>4</sub> yr<sup>-1</sup> less when the G2000 scheme is used. (Table 6, Table S1). In all mTCs, estimates of emissions from the major sources (either biospheric or anthropogenic) are more strongly affected by the convection schemes than the estimates of minor sources (L<sup>62</sup>T and L<sup>62</sup>G). In L<sup>78</sup>T, the effects of the convection schemes are not assessed in a strictly comparable setup, but similar results are expected (for a fair comparison assessed on short time period, see *Supplementary material*). Note that L<sup>78</sup>T and L<sup>78</sup>G-K have significantly different annual total emission estimates and their interannual variability in Asian temperate and Asian tropical regions (Fig. 8), but the difference in the convection schemes is not the main cause. Although the emission estimates for the SH are smaller in L<sup>62</sup>G than in L<sup>62</sup>T, SH posterior surface atmospheric CH<sub>4</sub> and XCH<sub>4</sub> are larger in L<sup>62</sup>G than in L<sup>62</sup>T, due to faster mixing and larger emission estimates in the NH. Agreement with independent observations is best in L<sup>62</sup>G among the inversions. NH surface atmospheric CH<sub>4</sub> in L<sup>62</sup>G are in good agreement with observations at in situ stations, and L<sup>62</sup>G XCH<sub>4</sub> also agrees best with the TCCON XCH<sub>4</sub> globally. Although NH XCH<sub>4</sub> in L<sup>62</sup>G is larger than in GOSAT retrievals, the results suggest that CTE-CH<sub>4</sub> performed better in TM5 when the G2000 scheme is used rather than T1989. It could be assumed that if GOSAT retrievals are assimilated in CTE-CH<sub>4</sub>, emission estimates will decrease in the NH and increase in the SH compared to this study. Also, the assimilation of satellite-based retrievals may reduce differences in the estimates between the L<sup>62</sup>T and L<sup>62</sup>G set-ups. However, the assimilation of GOSAT XCH<sub>4</sub> require further development as previous studies (Houweling *et al.*, 2014; Pandey *et al.*, 2016; Bergamaschi *et al.*, 2013) have shown that the biases in the GOSAT XCH<sub>4</sub> products could misrepresent the distribution and seasonal cycle of the optimized surface emissions.

## 4.2 Uncertainties in emission estimates

The smallest uncertainties in the posterior total annual emissions are generally seen in L<sup>62</sup>T, and the largest in L<sup>78</sup>T. We expected that L<sup>78</sup>T would have larger uncertainties than L<sup>62</sup>T and L<sup>62</sup>G. The prior uncertainties in L<sup>78</sup>T are the sum of both prior anthropogenic and biospheric uncertainty estimates for each optimization region, whereas the uncertainty in L<sup>62</sup>T and L<sup>62</sup>G is from either anthropogenic or biospheric emissions. Although the differences are small (<0.1%), uncertainties in the emission estimates in L<sup>62</sup>G are slightly larger than those in L<sup>62</sup>T in most of the optimization regions for both anthropogenic and biospheric emissions. It could be that there is more mixing of the surface signals in G2000, thereby producing a wider range of ensemble atmospheric CH<sub>4</sub> values, and thus L<sup>62</sup>G may have less flux sensitivity at surface sites. However, the difference in the ensemble standard deviation of atmospheric CH<sub>4</sub> values between inversions is small. Furthermore, this cannot be explained by the number of assimilated observations. The uncertainty is larger in L<sup>62</sup>G than in L<sup>62</sup>T, while the number of rejected observations is smaller in L<sup>62</sup>T than in L<sup>62</sup>G (6.6% and 6.9%). Similarly, the anthropogenic emission uncertainty is smaller for the Eurasian boreal region than for north-east Europe, which also cannot be explained purely by the number of observations within the region.

For most of the mTCs, anthropogenic emission estimates are larger than biospheric emission estimates, and reductions in uncertainties ( $\sigma_r^2 = 1 - \sigma_{posterior}^2 / \sigma_{prior}^2$ ) are also larger for anthropogenic emissions (L<sup>62</sup>T, L<sup>62</sup>G). However, for north-east Europe, the reduction in uncertainty for biospheric emission estimates is slightly larger, although the anthropogenic emission estimates are larger than biospheric emissions. This is partly the effect of the land-ecosystem map. Much of north-east Europe is defined as 'biospheric' land, i.e. inversions L<sup>62</sup>T and L<sup>62</sup>G can constrain the biospheric estimates more than the anthropogenic estimates. On the other hand, uncertainty reduction in L<sup>78</sup>T is not affected by the land-ecosystem map. Uncertainty reduction rates for biospheric and anthropogenic emission estimates in north-east Europe are similar in L<sup>78</sup>T. Although the posterior uncertainties are largest in the L<sup>78</sup>T estimates,  $\sigma_r^2$  is also generally the largest in the L<sup>78</sup>T. Note that the Chi-squared statistic for global estimates is 0.9 in L<sup>62</sup>T, which would indicate that the prior covariance structure is appropriate for this configuration. For L<sup>78</sup>T, the Chi-squared statistic is smaller (0.6), which indicates that the prior state covariance matrix with spatial correlation would probably be more appropriate than the diagonal covariance matrix for this configuration.

Emissions in the Eurasian boreal region are difficult to constrain because of the sparse observation network. Indeed, emissions for mTC7 are estimated not by local observations within the region, but rather by “background” observations that constrain total budget of larger area. The only observation site used in this study within mTC7 was Tiksi, Russia (TIK), where observations started in 2010. Although Tiksi is a good reference site for biospheric signals during summer and autumn, one station is not sufficient to constrain the emissions for the whole Eurasian boreal region. Additional observations from the National Institute for Environmental Studies (NIES) tall tower network (Sasakawa *et al.*, 2012) and the Zotino Tall Tower Observatory (ZOTTO) (Winderlich *et al.*, 2010) for example, would be useful to better understand the emissions from this

region. Those observations will be included in future studies. Nevertheless, the uncertainties for anthropogenic emissions are reduced by about 20% probably due to some influence of observations located in nearby mTCs.

The covariance structure of the posterior estimates is similar to the prior in all inversions. Taken in combination with the Chi-squared statistic (0.9 in  $L^{62}T$ ), this means either that the assumption in the prior covariance is good, or the inversions are not able to change much from the prior due to e.g. limited prior variation or observation coverage is too sparse. For mTCs such as the South American tropical region,  $L^{62}T$  and  $L^{62}G$  have a prior correlation between different LETs, but  $L^{78}T$  shows no correlation between optimization regions. The posterior correlations are similar to the prior in all inversions, i.e.  $L^{62}T$  and  $L^{62}G$  posterior have a strong correlation, however,  $L^{78}T$  has almost zero correlation as the dependencies are not well optimized by the inversions. On the other hand, similar posterior correlations between anthropogenic and water optimization regions are found for the Asian temperate mTC region, regardless of the prior assumption.  $L^{62}T$  and  $L^{62}G$  have a prior correlation of about 0.5, but the correlation is reduced to less than 0.1.  $L^{78}T$  has a prior correlation of zero, and the posterior correlation does not increase significantly, supporting the  $L^{62}T$  and  $L^{62}G$  posterior correlation. This suggests that the prior correlation for those optimization regions in  $L^{62}T$  and  $L^{62}G$  is probably too strong. In the prior covariance, no negative correlation was assumed between any scaling factors. However, some scaling factors are weakly negatively correlated in the posterior estimates. For example, anthropogenic emissions in the Asian temperate region are negatively correlated with those in the Atlantic Ocean in all inversions. This is one of the reasons why ocean emissions are sensitive to the estimates of nearby land regions (see Section 3.4.6). The inversions did not turn positive correlations into negative correlations.

## 5. Summary and Conclusions

We presented global and regional  $CH_4$  emission for 2000-2012 estimated using the CarbonTracker Europe- $CH_4$  (CTE- $CH_4$ ) data assimilation system. Estimates were evaluated against assimilated in situ atmospheric  $CH_4$  observations and model-independent atmospheric measurements from aircraft campaigns, as well as  $XCH_4$  retrievals from TCCON and GOSAT. Three inversions were performed to evaluate the effect of two configurations of CTE- $CH_4$ . The inversions differed by the number of scaling factors and the choice of convection scheme used in the TM5 atmospheric chemistry transport model. One configuration optimized either biospheric or anthropogenic emissions ( $L^{62}$ ) and the second optimized both ( $L^{78}$ ) in each optimization region. Interannual variability of the atmospheric  $CH_4$  sink was not taken into account in the inversions. We estimated total global posterior emissions for 2000-2012 at  $515\text{-}517\pm 44\text{-}62$  Tg  $CH_4$   $yr^{-1}$ . The estimated increase from 2001-2006 to 2007-2012 was 18-19 Tg  $CH_4$   $yr^{-1}$ , which was mainly driven by increased emissions in the modified TransCom (mTC) of the South American temperate, Asian temperate, and Asian tropical regions. This estimated increase in posterior total global  $CH_4$  emissions was more than 10 Tg  $CH_4$   $yr^{-1}$  less than in the prior. The inversions suggested that most of the increase was in anthropogenic rather than biospheric emission estimates. However, we could not confirm whether the increase was caused by

anthropogenic or biospheric emissions. The inversions had a tendency to optimize regions with major sources, and anthropogenic emission estimates were often larger than biospheric emissions in optimization regions.

Furthermore, posterior emissions were generally smaller than prior emissions in the high latitudes of the NH (North American boreal region, Europe and Eurasian boreal regions), whereas posterior emissions were larger than the prior emissions in Africa and the SH (northern Africa, southern Africa, South American temperate and Australia). For the Tropics (South American tropical and Asian tropical mTC regions), posterior emissions were similar or slightly lower than the prior emissions. This was consistent in all inversions, i.e. the spatial distribution in the prior emissions, probably for anthropogenic sources, may need to be revised with less emissions in the mid-latitude NH and more emissions in temperate regions in the SH.

10

The study focused on Europe in more detail by dividing it into four mTCs: south-east, south-west, north-east, and north-west Europe. Neither prior nor posterior emissions showed any significant trends in anthropogenic or biospheric emission estimates in Europe as a whole. However, the posterior anthropogenic emissions were larger than the estimates in EDGAR v4.2 FT2010 inventory for southern Europe, while they were lower in northern Europe. Also, the posterior biospheric emission estimates show different interannual variability than those from the LPX-Bern vegetation model, such that CTE-CH<sub>4</sub> estimates agreed better with CH<sub>4</sub> emissions measured at some wetland sites. Furthermore, the application of different scaling factors to regions divided by land-ecosystem type was an improvement. This approach could be useful to better understand the dependence of CH<sub>4</sub> emissions on meteorological parameters for different ecosystem types, and development of the approach will continue. Posterior emissions in Europe were similar regardless of whether only anthropogenic or biospheric emissions were optimized, or both categories were optimized in each optimization region. Total emissions were similar and the ratio of anthropogenic to biospheric estimates did not change much from the prior.

15  
20

In the Asian temperate and Asian tropical regions, L<sup>62</sup> configuration was found to be more consistent with observations, and it produced more reasonable emission estimates. On the other hand, L<sup>78</sup> configuration was better where both anthropogenic and biospheric emissions were large or the land-ecosystem map was badly defined, such as Australia.

25

Evaluations with in situ observations showed that the inversions successfully reduced the bias between observed and estimated CH<sub>4</sub> abundance from the prior to the posterior. A comparison with model-independent retrievals of XCH<sub>4</sub> from TCCON and GOSAT showed that agreement in posterior XCH<sub>4</sub> was especially good in the NH. However, negative biases in XCH<sub>4</sub> were found in the SH in all inversions, although the seasonal cycle at the TCCON sites was well captured. This suggests that there are some emissions that were not optimized well by CTE-CH<sub>4</sub>, although possible errors in the vertical or stratospheric distributions due to the transport model cannot be ignored. The evaluation also revealed that TM5 with the G2000 convection scheme produces larger emission estimates in the NH and smaller emissions in the SH when compared to the T1989 convection scheme. With the G2000 convection scheme, transport from the NH to the SH was faster, leading to smaller inferred SH

30

emissions and larger NH emissions. This means that the posterior emissions were closer to the prior in the SH than in the NH when the G2000 convection scheme was used. Furthermore, posterior atmospheric CH<sub>4</sub> values agreed slightly better with observations when the G2000 convection scheme was used. In addition, evaluation with GOSAT XCH<sub>4</sub> revealed that the spring peaks in XCH<sub>4</sub> in the tropics were poorly captured in inversions that used the T1989 convection scheme. This feature was best captured in the inversion using the G2000 convection scheme, which estimated larger NH winter emissions than the inversions that used the T1989 convection scheme.

#### Key messages:

- Global and regional CH<sub>4</sub> emissions for 2000-2012 were estimated using CTE-CH<sub>4</sub> to examine the cause of increase in atmospheric CH<sub>4</sub> after 2007.
- 18-19 Tg CH<sub>4</sub> yr<sup>-1</sup> increase in the global CH<sub>4</sub> emissions was needed from before 2007 to after 2007 to match the increase in the observed atmospheric CH<sub>4</sub> growth rate of about 6 ppb yr<sup>-1</sup> (without taking into account the interannual variability of the atmospheric CH<sub>4</sub> sink).
- We found the main increase in emissions was located in South American temperate and Asian temperate regions but contributions from either biospheric or anthropogenic sources could not be concluded.
- Agreement of posterior atmospheric CH<sub>4</sub> values with in situ observations and aircraft observations, and of posterior XCH<sub>4</sub> with TCCON and GOSAT retrievals was good. Agreement was better when the Gregory *et al.* (2000) convection scheme was used.
- A large increase in anthropogenic CH<sub>4</sub> emissions from temperate North America was not needed to match observations.

#### Code and data availability

The source code of CTE-CH<sub>4</sub> and data presented in this paper are part of the CTDAS code repository maintained by Wageningen University & Research, and all model results and code will be provided on request from the corresponding author (Aki Tsuruta: Aki.Tsuruta@fmi.fi).

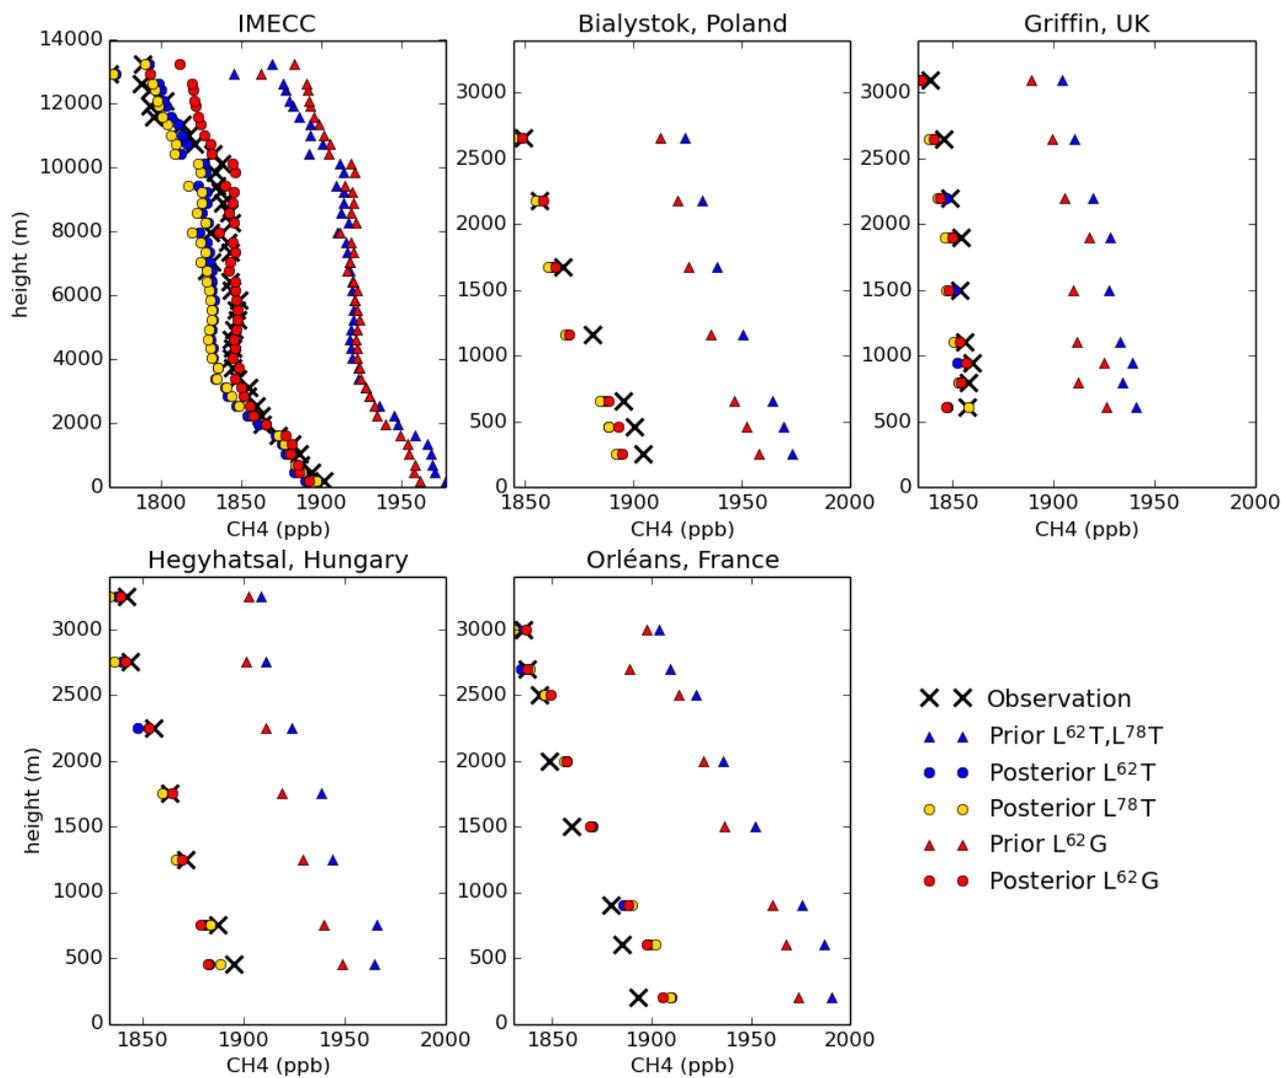

**Figure 1.** Modified TransCom (mTC) regions illustrated in numbers and colours and locations of sites with observations assimilated in the inversions. The names of the mTCs regions are given in Table 5.

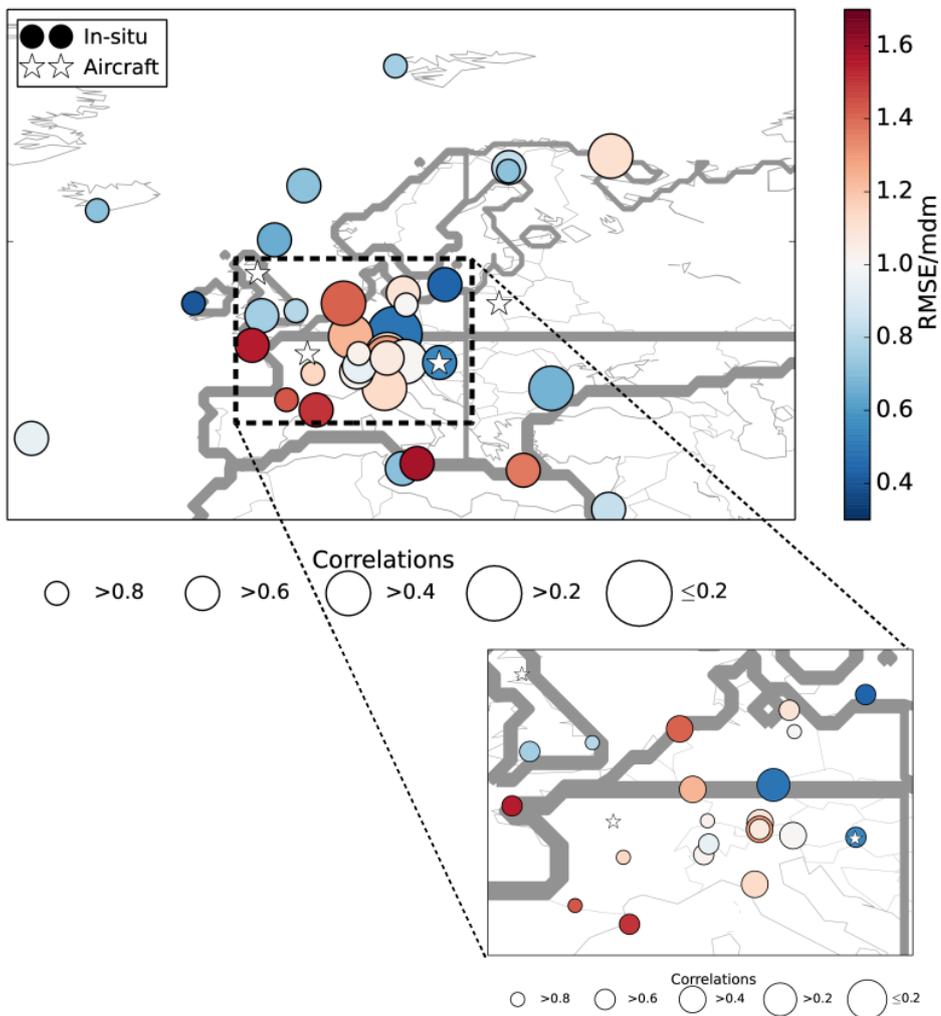

**Figure 2.** Differences in CH<sub>4</sub> (ppb) between the assimilated observations and model estimates.

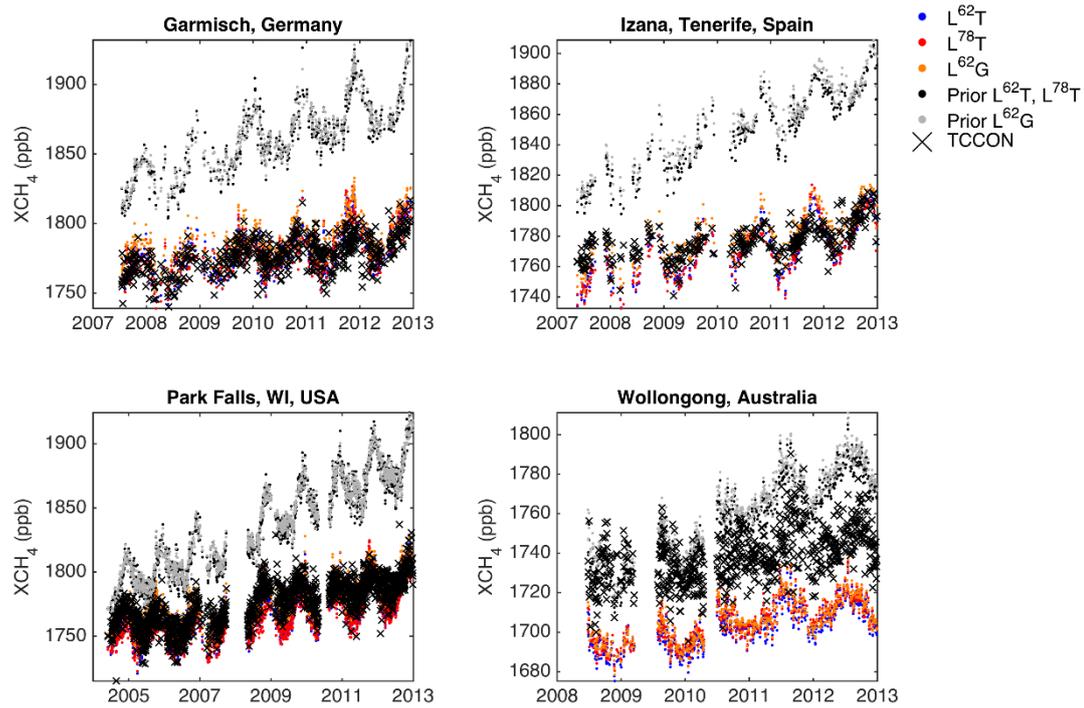

**Figure 3.** Top: simulated global mean  $XCH_4$ , (LH y-axis) and NOAA globally averaged surface  $CH_4$  (RH y-axis). Bottom: growth rates of simulated  $XCH_4$ , and of observed  $CH_4$ . The growth rates were calculated using the methods in Thoning *et al.* (1989). Vertical and horizontal lines indicate 2007 and zero GR to guide the eye, respectively.

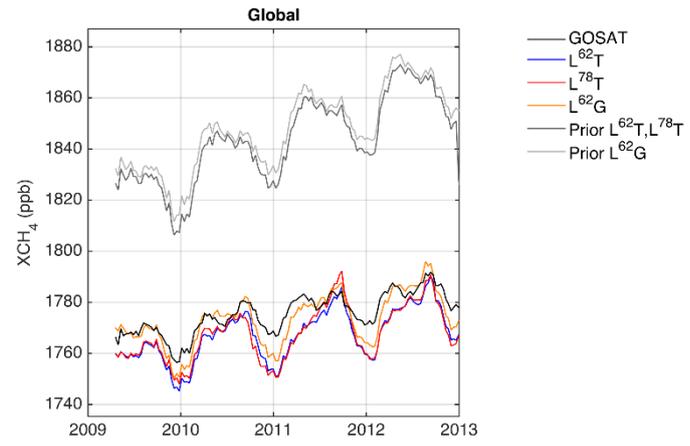

**Figure 4.** Vertical profiles of atmospheric CH<sub>4</sub> (ppb) from aircraft and posterior estimates. For each site, the medians were calculated and plotted for both observations and posterior estimates for each altitude band.

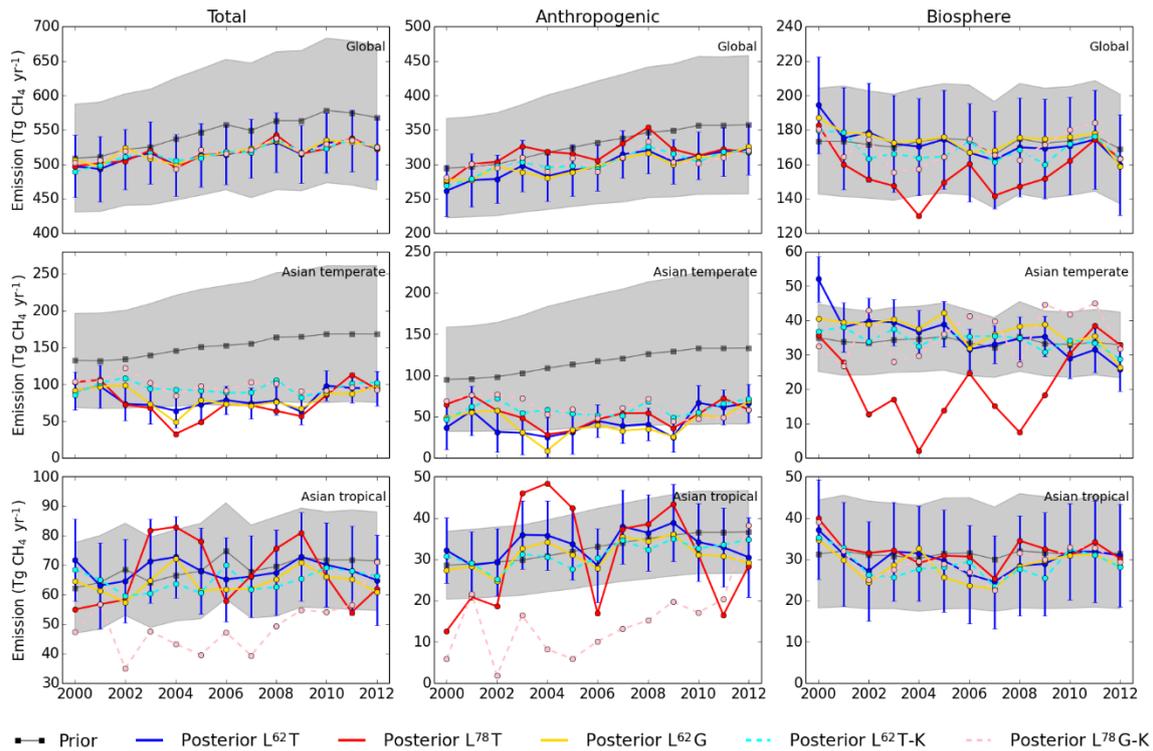

**Figure 5.** Performance of inversion  $L^{62}G$  at European in situ observation sites, whose data were assimilated in the model, and at the locations of four aircraft campaigns. The campaign locations are marked with stars. Aircraft observations were used for evaluation. The colour of the marker for the in situ observation site is determined by the RMSE of observed and simulated posterior atmospheric  $CH_4$  values divided by the pre-defined  $mdm$ . The radius of each circle provides the correlation between observed and simulated posterior atmospheric  $CH_4$  values, where a larger radius corresponds to weaker correlation. Thick grey lines identify the mTC borders.

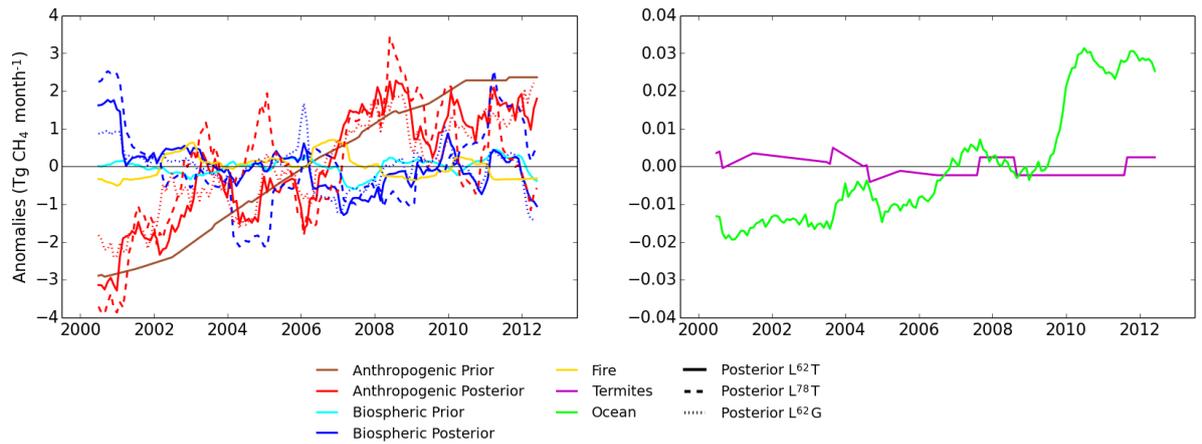

**Figure 6.** Observed and simulated daily mean XCH<sub>4</sub> at TCCON sites.

**Figure 7.** Global GOSAT and simulated regional 10-day mean XCH<sub>4</sub>.

**Figure 8.** Prior and posterior regional annual emission estimates for global, Asian temperate and Asian tropical regions. Shaded areas are prior uncertainties, and vertical bars illustrate L<sup>62</sup>T posterior uncertainties. The uncertainties are 1 standard deviation of ensemble distributions. Note different ranges on the y-axes.

**Figure 9.** Anomalies of 12-month moving averages of monthly mean emission estimates from five sources. Note that ocean emissions are only from natural sources, i.e. anthropogenic emissions over the ocean are included in anthropogenic emission. Zero levels shown by black lines are the mean of the 2000-2012 moving averages.

**Table 1.** List of inversion set-ups.

Inversion	Number of parameters and optimized sources*	TM5 convection
L <sup>62</sup> T	62, anthropogenic OR biospheric	Tiedtke (1989)
L <sup>78</sup> T	78, anthropogenic AND biospheric	Tiedtke (1989)
L <sup>62</sup> G	62, anthropogenic OR biospheric	Gregory <i>et al.</i> (2000)

\* Optimized sources per optimization region

**Table 2.** List of surface in situ observation sites used in inversions. Model-data-mismatch (mdm) is used in the observation covariance matrix, and defining rejection threshold of the observations. Data type is categorized into two: discrete (D) and continuous (C) measurements. \*Date range is only presented since Jan. 1999 until Dec. 2014. Note that some sites have longer records.

**Table 6.** Mean emission estimates and their uncertainties before and after 2007 (Tg CH<sub>4</sub> yr<sup>-1</sup>). The uncertainties are 1 standard deviation of ensemble distributions. Prior uncertainties are from inversion L<sup>62</sup>T and L<sup>62</sup>G, i.e. of CTE-CH<sub>4</sub> v1.0. L<sup>78</sup>T (CTE-CH<sub>4</sub> v1.1) has larger prior uncertainties in all regions due to its set-up. For other regions, see *Supplementary material*. Emission estimates after 2007 that are more than 1 Tg CH<sub>4</sub> yr<sup>-1</sup> larger than those before 2007 are marked in bold.
