Abstract. A simple plume implementation of the second version (v2) of the Max Planck Institute Aerosol Climatology, MACv2-SP, is described. MACv2-SP provides a prescription of anthropogenic aerosol optical properties and an associated Twomey effect for the harmonized use in climate modelling studies. It has been designed to be easy to implement, change and use, and thereby enable studies exploring the climatic effects of different plausible aerosol distributions and their impact on

5   clouds. MACv2-SP is formulated in terms of nine spatial plumes associated with different major anthropogenic source regions. The shape of the plumes is fit to the Max Planck Institute Aerosol Climatology, version 2, which is based on present day (2005) observations. Decadal variations in the amplitude of the plumes over the historical (post 1850) period is derived by scaling the plumes with associated national emission sources of SO_2 and NH_3. Two types of plumes are considered: one predominantly associated with biomass burning the other with industrial emissions. The two types of plumes differ in the prescription of their

10   annual cycle and in their optical properties, thereby implicitly accounting for different contributions of absorbing aerosol to the different plumes. A Twomey effect for each plume is prescribed as a change in the host model's background cloud droplet population density using relationships derived from satellite data. Experiments using the simple plume model are performed with the Max Planck Institute Earth System Model. The instantaneous and effective aerosol radiative forcings is estimated to be $-0.6\,\mathrm{W\,m^{-2}}$ and $-0.7\,\mathrm{W\,m^{-2}}$ respectively. Forcing from aerosol-cloud interactions (the Twomey effect) offsets the reduction

15   of clear-sky forcing from clouds, so that the net effect of clouds on the aerosol forcing is small.

1   Introduction

Attempts to understand how the anthropogenic aerosol affects the climate system have tended to focus on the quantification of aerosol radiative forcing. One way to do this is to characterize the physical properties of the aerosol given knowledge of aerosol and aerosol precursor emissions. Given the aerosol physical properties, optical and cloud active properties can then

20   be specified and used to quantify aerosol radiative forcing. This 'bottom-up' approach has proved challenging. One reason is that important aerosol processes remain poorly understood (Boucher et al., 2013; Carslaw et al., 2013). Another reason is the enormous scale divide between the processes that are understood and what can be represented with fidelity in a large-scale model – even processes that are well understood prove difficult to implement consistently (e.g., Stevens and Feingold, 2009).

From this perspective it is not surprising that independent efforts adopting 'bottom-up' approaches yield estimates of aerosol radiative forcing that differ widely (Shindell et al., 2013; Myhre et al., 2013; Boucher et al., 2013).

Rather than asking how our understanding of aerosol processes constrains aerosol-radiative forcing, a 'top-down' approach
5   takes a given distribution of aerosol optical and cloud active properties and asks to what extent is it consistent with the expected response of the climate system to forcing this distribution implies. Present bounds on aerosol radiative forcing are largely a result of such approaches (Murphy et al., 2009; Stevens, 2015). The goal of the paper is to describe a simple and easy to implement aerosol-climatology that we have developed to help advance the 'top-down' approach for constraining aerosol radiative forcing.

10   The idea of using the response of the climate system to a hypothetical (aerosol) forcing as a test of that forcing is at the heart of detection and attribution studies, and presupposes some understanding of the pattern of aerosol forcing and the pattern of the response. For instance, it has been argued that a strong aerosol forcing, which would have been disproportionally concentrated around the source regions in the Northern Hemisphere is inconsistent with the strong pattern of Northern Hemisphere warming through the first part of the last century (Stevens, 2015). But this argument assumes that warming in the Northern Hemisphere,
15   especially in the Atlantic sector, could not have been as large as was observed if the net radiative forcing over the hemisphere, or region, was negative. This need not be the case, as enthalpy may have been imported into the region at a rate that more than offsets the local negative forcing. But to test the idea it would be helpful to see if robust climate responses can be attributed to patterns of aerosol forcing, for which the ability to prescribe the same pattern of forcing across many climate models is a pre-requisite.

20   Given that the twentieth century witnessed a large human imprint on the atmospheric aerosol, it seems natural to ask what was different about the climate of the twentieth century due to this anthropogenic aerosol. Published studies, usually based on the response of an individual model, hint that aerosol perturbations may be responsible for shifts in patterns of monsoon rainfall (Bollasina et al., 2011), decadal variability in the Atlantic which may have led to a possible suppression of hurricane activity (Khain et al., 2010), diminished sunlight at the surface over Europe (Wild, 2012) and the conspicuous decrease in
25   temperature over the eastern and central United States during the middle of the last century (Leibensperger et al., 2012). But these ideas have proven controversial: the response of the ITCZ is sensitive to the representation of the cloud processes (Voigt et al., 2014); a purportedly strong North Atlantic cooling by the aerosol appears to be inconsistent with the sub-surface temperature record (Zhang et al., 2013); and variations in the surface energy budget are difficult to extract from the noise of natural variability, particularly at high-latitudes (Deser et al., 2014). Coincident shifts in large-scale modes of natural variability
30   confound attempts to link climate responses to aerosol forcing. For example, the Pacific Decadal Oscillation, changed sign in the 1970s at the same time that aerosol-forcing is thought to have maximized over the Atlantic sector (Meehl et al., 2009). Clearly a deeper understanding of how the climate system responds to regional heating anomalies would provide a stronger foundation for quantifying the role of aerosol forcing. Toward this end a simple method for prescribing aerosol-like anomalies in atmospheric composition would be useful.

35   These thoughts motivated us to develop a simple parameterization of anthropogenic aerosol optical properties and the effect of the anthropogenic aerosol on the radiative properties of clouds for use in climate models. Our goal is to develop an analytic

description of the anthropogenic aerosol with realistic, albeit climatological, variability in space and time, as well as spectral dependence. Similar, albeit even more simplistic approaches have been attempted in the past (Tanré et al., 1984), but not for the purpose of studying aerosol changes, and without the benefit of modern observations. Our chosen description would

5 be fit to the present day observational record, and scaled backward and forward in time to capture past or future changes in aerosol and aerosol precursor emissions. An analytic, albeit empirical, description was desirable to avoid re-gridding a base climatology for a particular model resolution, and to reduce the input data volume, particularly given the importance and emphasis on the use of higher-resolution simulations in the future. An ability to vary the aerosol properties over time is necessary to represent scenarios of past and possible future effects of anthropogenic activity. In contrast to comprehensive

10 aerosol-chemistry-climate models we sought an approach that would be easy to implement, computationally efficient, and easy to modify so as to encourage experimentation on the one hand, and easily incorporate new understanding on the other hand. By describing the aerosol in terms of its optical properties and its effect on cloud droplet population densities we reduce the chance of introducing discrepancies in forcing that may arise from different choices for how to couple parameterizations of aerosol physical properties to parameterizations of clouds and radiation. It is our hope that the methods we develop will provide

15 a welcome complement to comprehensive aerosol models, spur research into how the climate system responds to forcing, and help clarify what degree of detail in the representation of aerosol radiative forcing can lead to a response that is measurable against the noisy background of natural variability.

The organization of the paper is as follows. In Section 2 we describe the aerosol-distribution component of the parameterization, which is developed and fit to an observational climatology developed for the year 2005. In Section 3 we propose

20 an approach for linking anthropogenic aerosol optical depth to changes in cloud active properties. Our representation of the 2005 aerosol distribution and aerosol radiative effects, including induced changes on the scattering cross section (albedo) of clouds, is evaluated in Section 4 using global simulations with the Max Planck Institute Earth System Model, the MPI-ESM. In section 5 we describe a procedure for scaling the 2005 climatology over the historical period using anthropogenic aerosol and aerosol-precursor emission estimates from different geographic regions, and show how a similar approach can be adopted

25 to projected future emissions. The approach and our main results are summarized in Section 6.

2 Simple plumes as basis functions for representing anthropogenic aerosols

Our basic idea is to associate spatial plumes of anthropogenic aerosols with emissions from source regions. The plumes are constructed by fitting to observationally based estimates of the present day (2005) distribution of anthropogenic aerosol optical depths in the mid-visible (550 nm). To capture past changes the amplitude of these plumes will be scaled with the strength of the

30 anthropogenic emissions within the source region. Unlike natural aerosol emissions, which in many cases are well distributed (for instance from wind driven sources over the ocean or arid land) anthropogenic emissions are spatially compact, at least from a planetary perspective. This motivates the adoption of a small number of plumes, as basis functions for representing anthropogenic aerosol optical, and cloud-active, properties. For simplicity we consider two plume types, one that is dominated by emissions from industrial emissions, the other from biomass burning. Hereafter we refer to these as industrial and biomass

plumes respectively, even though each plume really composites over a mixture of source activities. The industrial and biomass plumes are distinguished by the strength of their seasonal cycle, their absorption single-scattering albedo, and the degree to which an optical depth perturbation is associated with a change in cloud-droplet population densities.

5   The plumes are designed to fit the 2005 distribution of mid-visible anthropogenic aerosol optical depth as described by the Max Planck Institute Aerosol Climatology, MAC (Kinne et al., 2013). Version 2 of this climatology, MACv2 (Kinne et al., 2016, manuscript in preparation) provides estimates of monthly-mean aerosol optical properties at a spatial resolution of $1°$ of latitude by $1°$ of longitude. Climatological values of aerosol properties are derived from high-quality data by ground-based sun-photometer networks merged onto background maps from global models participating in the Aerosol Model Intercomparison

10   project (AeroCom). The merging is performed for different aerosol properties: AOD at 440 nm, 550 nm, 870 nm, absorbing AOD at 550 nm, and for that component of the AOD at 550 nm associated with either just super-micrometer (coarse-mode) sized particles or sub-micrometer (fine-mode) sized aerosol particles. The merged fine-mode AOD (at 550 nm) along with a scaling factor based on fine-mode AOD output of comprehensive aerosol-chemistry models run for present-day and pre-industrial conditions define the anthropogenic AOD (at 550 nm) map of MACv2. This map is subsequently approximated by

15   the plume-concept of MACv2-SP. MACv2 differs from MACv1 (Kinne at al., 2013) in that: (i) oceanic reference data are now included; (ii) only absolute aerosol optical properties are now merged; and (iii) on average ca 30 % lower anthropogenic fine-mode AOD contributions are assumed. Adopting simple plumes as basis functions to represent the anthropogenic aerosol could be adapted to any climatology, but to reflect its origins in MACv2, hereafter we refer to our model as MACv2-SP.

Nine plumes (five industrial and four biomass) appears to adequately capture the spatial distribution of the anthropogenic

20   aerosol of MACv2. The names given to the individual plumes, the location of the plume centers and the type of each plume is summarized in Table 1 and illustrated in Fig. 1 relative to the 2005 annual-mean of MACv2. Note that the distinction between the North African and the South-Central African plume is small, as the two plumes form a couple to better represent the shifting location of the AOD maximum in the annual cycle.

A basic premise in the development of MACv2-SP is that the shape of individual plumes is independent of the strength of

25   the source. This is a reasonable assumption as long as changes in the atmospheric circulation are expected to be small relative to uncertainty in the aerosol pattern for a given source. Such an assumption is supported by the lack of evidence of strong coupling between climate and aerosol forcing (Boucher et al., 2013). Even so a climatology necessarily omits the coupling between synoptic systems and the aerosol, which is quite likely to be important to the aerosol effect: experience suggests that rainier days are cloudier, but also less aerosol laden. This implies that prescribing the time mean aerosol may result in a larger

30   radiative forcing than would arise from an aerosol with the same time-mean properties, but which was allowed to interact with the circulation, i.e., the bistability hypothesis of Baker and Charlson (1990). These moderating effects are accounted for in MACv2-SP by setting the spatial and seasonal *pattern* of the aerosol based on MACv2, but allowing a degree of freedom in the specification of its *amplitude*. In MACv2-SP the exact amplitude of the forcing plays a secondary role, as the idea is to use the flexibility of the parameterization to see what amplitude of aerosol radiative forcing is consistent with the instrumental record, as studies using a similar but yet simpler approach (e.g., Stevens, 2015; Pincus et al., 2016) have suggested that this may help provide better bounds on the magnitude of aerosol radiative forcing.

Model Development
Discussions

Mathematically, MACv2-SP provides a five dimensional (three spatial, time and wavelength) description of the anthropogenic aerosol optical properties. For the anthropogenic optical depth, τ_{a}, it takes the following form:

$$\tau_{\mathrm{a}}(x,y,z,t,\lambda) = \sum_{i=1}^{9} s_i(x,y,z,t_{\mathrm{f}}(t)) E_i(t_{\mathrm{y}}(t)) A(\lambda) \tag{1}$$

where s_i defines the aerosol optical depth in the mid-visible (550 nm) as a function of space and time of year, whereby

$$t_{\mathrm{f}}(t) := t \qquad \mathrm{mod}\ 1\mathrm{y}. \tag{2}$$

The other independent variables are the three-dimensional spatial coordinates (x,y,z), measured in degrees of longitude and latitude in the horizontal and meters in the vertical, and the wavelength λ. Year to year variation in the amplitude of the ith plume is described by E_i whereby $t_{\mathrm{y}}(t) := \lfloor t/1\mathrm{y} \rfloor$ denotes calendar year, so that $t = t_{\mathrm{y}}(t) + t_{\mathrm{f}}(t)$. The aerosol optical depth spectral (wavelength) dependance is defined by the Ångström parameter α through the factor

$$A(\lambda) = \exp\left[-\alpha \ln\left(\frac{\lambda[\mathrm{nm}]}{550\,\mathrm{nm}}\right)\right], \tag{3}$$

which may vary from plume to plume. In the following subsections we describe how s_i is specified, followed by a description of the wavelength-dependence of the optical depth as well as single scattering albedo and the asymmetry factor.

2.1 Plume spatial structure

The spatial structure of the anthropogenic aerosol optical depth at 550 nm is given through the superposition of an arbitrary number of individual *features* (or sub-plumes) weighted by an annual cycle. For these features we have chosen rotated Gaussian functions, such that

$$s_i(x,y,z,t_{\mathrm{f}}) = \tau_i^*\left[b_i(x,y,z)\sum_{j=1}^{2} a_{ij}(t_{\mathrm{f}}) \exp\left(-\frac{1}{2}\langle \mathbf{x}_i, \mathbf{R}_{ij}\mathbf{A}_{ij}^{-1}\mathbf{R}_{ij}^{-1}\mathbf{x}_i \rangle\right)\right], \qquad \mathbf{x}_i = \begin{pmatrix} x - x_i \\ y - y_i \end{pmatrix}. \tag{4}$$

Here i denotes the plume number, j the feature number, $a_{ij}(t_{\mathrm{f}})$ is the feature weighting in an annual cycle, $b_i(x,y,z)$ the vertical weighting, τ_i^* the column optical depth of the ith plume at its center in the reference year (2005), and (x_i, y_i) the latitude and longitude of the plume centers. The feature weighting satisfies $\sum_j \int_0^1 a_{ij}(t_{\mathrm{f}})\,\mathrm{d}t_{\mathrm{f}} = 1$. The feature weights a_{ij} are split into time weights $w_{ij}(t_{\mathrm{f}})$ describing the pure annual cycle and relative feature weights f_{ij} giving a specific weight to each feature in a plume such that $a_{ij}(t_{\mathrm{f}}) = f_{ij} w_{ij}(t_{\mathrm{f}})$. The feature weights are plume-dependent and are chosen such that the pattern of MACv2 is reproduced and τ of MACv2 matches that at the plume center. Two features are adopted for each plume to better represent the near and far-field aerosol distributions as seen in MACv2.

2.1.1 Horizontal structure

From Eq. (4) it is apparent that the horizontal structure of an individual plume is the composite of two gaussians. One is chosen to be rotationally symmetric, the other elongated to mimic transport with prevailing winds and asymmetric distributions of

Geoscientific
Model Development
Discussions

5 sources and sinks. The covariance matrix $\mathbf{A}_{ij}$ describes the latitudinal and longitudinal extent of each gaussian feature such
that:

$$
\mathbf{A}_{ij} = \begin{cases} \begin{pmatrix} \sigma_{\mathrm{W},ij}^2 & 0 \\ 0 & \sigma_{\mathrm{W},ij}^2 \end{pmatrix}, & \text{if } (x - x_i) \leq 0 \\[2em] \begin{pmatrix} \sigma_{\mathrm{E},ij}^2 & 0 \\ 0 & \sigma_{\mathrm{E},ij}^2 \end{pmatrix}, & \text{if } (x - x_i) > 0. \end{cases}
\tag{5}
$$

The components of $\mathbf{A}_{ij}$ are chosen subjectively for each plume so as to reasonably fit the climatology. For each plume, one
of the gaussian features is associated with the near-field in the source region. A rotationally-symmetric form provided a good

10 match to the near-field response. This makes physical sense, as the source is really a dispersion of sources over a region, and
transport within the region is likely to be more influenced by deviations from the prevailing wind. Long-range transport, which
is determined more by the influence of the prevailing winds, is represented by the second feature.

The horizontal orientation of the plumes is also controlled by the rotation matrix $\mathbf{R}_{ij}$:

$$
\mathbf{R}_{ij} = \begin{pmatrix} \cos(\theta_{ij}) & -\sin(\theta_{ij}) \\ \sin(\theta_{ij}) & \cos(\theta_{ij}) \end{pmatrix}.
\tag{6}
$$

15 The angles θ_{ij} are tuned for each plume and feature to match the dominant transport pathways, and the distribution of individual
sources within a source region as reflected by the monthly MACv2 climatology. For instance, the mid-latitude plumes point
northeastward from the centres, motivated by the aerosol transport with prevailing westerlies, and in the case of North America
the distribution of sources within the source region.

Adopting simple plumes as basis functions for representing the aerosol reasonably captures the spatial patterns of the ob-
20 served plumes. This is illustrated by Fig. 2, whose left panel first shows the structure of a single (East Asian) plume for the
month of September 2005. Here many features of the plume construction are evident, e.g., the asymmetry and the rotation of
its major axis relative to the cardinal directions. The composite structure that emerges when all nine-plumes are activated is
also shown in Fig. 2 (right). Here eight plume centers can be identified, with the East Asian, Indian and Indonesian biomass
plume forming a tri-polar structure. The North African plume is weak during boreal summer and subsumed in the south-central
25 African plume so that it is not evident as a distinct feature.

More quantitatively Fig. 3 compares $\langle \overline{\tau}_{550} \rangle$, with angle brackets denoting a column integral and over-bar a horizontal aver-
age, with that from MACv2. The horizontal average is over the latitudes from 30-60 °N. It suggests that the degrees of freedom
used to describe each plume provide a reasonable representation of the spatial structure as represented in the original MACv2
climatology.

Geoscientific
Model Development
Discussions

2.1.2 Vertical structure

The vertically integrated aerosol optical depth is distributed over height by b_i, chosen as the kernel of Euler's Beta function

5    $(B(p,q) = \int_0^1 \eta^{p-1}(1-\eta)^{q-1}\,\mathrm{d}\eta)$, modified by Heaviside's function, $\mathcal{H}$, to ensure that the plume vanishes at heights below the surface. Thus

$$b_i(x,y,z;p_i,q_i) = \left(\frac{\eta^{p_i-1}(1-\eta)^{q_i-1}}{B(p_i,q_i)}\right)\mathcal{H}(z - z_\mathrm{g}(x,y)), \quad \text{with} \quad \eta = \begin{cases} z/z_\mathrm{max} & \text{if } z \le z_\mathrm{max} \\ 0 & \text{otherwise} \end{cases} \qquad (7)$$

The parameters p_i, and q_i define the kernel of the Beta function for the ith plume and are tuned to reproduce the vertical distribution of the fine-mode AOD averaged in the surrounding area of $20° \times 20°$ in latitude and longitude of each plume

10   center; z_max is specified at 15 km to ensure that the plume does not extend into the middle and upper atmosphere, where its shape would no longer be constrained by the processes in the troposphere. Normalization by the Beta function, $B(p_i,q_i)$, ensures that the vertical weighting does not change the column optical depth, except in the case $z(x,y)$ extends below the surface. In the implementation the discrete integral of the Beta function is formed to ensure that this relation is also satisfied discretely. Prescribing the vertical distribution in this manner, whereby the vertical weighting is first defined from the distance

15   above the sea-surface, ensures that plumes whose origins are in low lying areas (which is the case for each of our plumes) do not unrealistically extend over neighboring topography, as they would otherwise, e.g., over South-East Asia, for instance (Fig. 2). It implies that the total column aerosol optical depth is reduced over elevated terrain. If the climatology were to be extended to include elevated source regions this prescription should be modified.

     Figure 4 shows b_i for three plumes compared to the fractions from MACv2.0. The largest extinction occurs in low-levels

20   for all plumes. Maxima in the tropics, e.g. Central Africa shown in Figure 4c, are shifted to higher altitudes compared to the extra-tropics, e.g. China and Europe (Figure 4a−b), consistent with deeper mixing over Africa, particularly in the dry season.

2.2 Annual cycle

Individual plumes can have their own annual cycle, which is assumed to only be determined by meteorology (and would include the timing of open burning), so that its amplitude relative to the annual mean can be assumed to be roughly constant

25   from one year to the next. The annual cycle is fit to MACv2, and is particularly pronounced over biomass burning regions.

     For all but two plumes the same time weights w_{ij} are applied to both of its features. The exceptions are the South American and South African plumes which have features with different annual cycles. The annual mean value of the time weights is specified to be unity, i.e., $\int_0^1 w_{ij}(t_\mathrm{f})\,\mathrm{d}t_\mathrm{f} = 1$. Currently we define two types of annual cycles, a small one for industrial plumes which is given as a harmonic perturbation about a mean

30    $w_{ij}(t_\mathrm{f}) = 1 - c_{ij}\cos\left(n\pi(t_\mathrm{f} - \phi_{ij})\right).$ (8)

with c_{ij} the annual component and ϕ_{ij} the phase. Here n is an integer. For all but the East Asian plume $n = 2$, defining a single annual cycle. For East Asia $n = 4$ thereby leading to two maxima and two minima, e.g., Table 1. The second type of annual

cycle is given by linearly interpolating to specified monthly values to fit the non-harmonic annual cycle of biomass burning plumes.

Figure 5 shows the monthly mean of the globally averaged τ_a and that just for latitudes equatorward of $15°$ to illustrate the
5 effect of the seasonal scaling. The global annual cycle is mostly carried by the biomass burning plumes in the deep tropics. These biomass plumes are most pronounced in the boreal summer, or the dry season over tropical land masses in the southern hemisphere. It remains debatable as to whether the annual cycle in aerosol forcing projects detectably onto the climate system, something that MACv2-SP can be easily used to test.

2.3 Wavelength dependent optical properties

10 The effect of the aerosol on radiative transfer requires spectral dependent information for the aerosol optical depth, asymmetry factor and single-scattering albedo of the aerosol. Because the anthropogenic aerosol is assumed to be small in size (ca. $0.15\,\mu$m in radius), the Ångström parameter is near 2.0, the asymmetry-factor is near 0.63 and only interactions with radiation at solar wavelengths is accounted for. For the single-scattering albedo, properties averaged over $20°$ latitude by $20°$ longitude regions around plume centers suggest than typical values are 0.93 for urban pollution and 0.87 for seasonal biomass burning,
15 as summarized in Table 2.. The solar dependence of the AOD is defined by the Ångström coefficient. For the single scattering albedo and the asymmetry factor the values at $550\,$nm apply for entire ultra-violet and visible regions of the solar spectrum (0.2-0.7 μm) but are reduced in the near-infrared region (0.7-3.0 μm) as the small aerosol size requires a reduction to both single-scattering albedo and the asymmetry factor in the Rayleigh limit. For the wavelength dependence of the single-scattering albedo $\omega_i(\lambda)$ of the plume i, we thus assume that

20
$$\omega_i(\lambda) = \left(\frac{\omega_{i,550}\Lambda^{-4}}{\omega_{i,550}\Lambda^{-4} + (1-\omega_{i,550})\,\Lambda^{-1}} \right) \cdot \mathcal{H}(\Lambda - 1), \quad \text{where} \quad \Lambda = \lambda/700\,\text{nm}, \tag{9}$$

and $\mathcal{H}$ is the Heaviside function, which indicates that the function is only applied for $\Lambda > 1$, or λ larger than $700\,$nm. This expression is motivated by the fact that, in the Rayleigh limit, absorption is inversely proportional to λ and scattering scales with λ^{-4} and absorption. The asymmetry parameter $\gamma_i(\lambda)$ is likewise adjusted for wavelengths larger than $700\,$nm such that:

$$\gamma_i(\lambda) = \Lambda^{-1/2}\gamma_{i,550} \cdot \mathcal{H}(\Lambda - 1). \tag{10}$$

25 In all cases the effect of the aerosol on the long-wave transfer of radiant energy is neglected, consistent with the assumption that the anthropogenic aerosol predominates in the fine mode. The final spatial optical properties arising from the superposition of different plumes calculated as is customary, i.e., by optical depth weighting.

As indicated in Eq (1), the wavelength dependence of the optical depth is derived by adopting an Ångström coefficient α. Scattering properties are adjusted for wavelengths larger than $700\,$nm only, motivated by the steep increase in aerosol absorption
30 toward the near infrared. For the wavelength dependence of the single-scattering albedo $\omega_i(\lambda)$ of the plume i, we assume

3 Cloud-active properties

To derive a relationship between the anthropogenic aerosol and cloud properties we first explored the relationship between the fine-mode aerosol optical depth τ_f and cloud-droplet population densities, N. The spatial association between estimates of the two quantities are available from satellite observations and from modelling. Three different satellite datasets, each with a spatial resolution of 1 ° in latitude and longitude, are considered. Two different processing versions of the MODIS (Moderate Resolution Imaging Spectroradiometer) sensor data and one based on the AATSR (Advanced Along Track Scanning Radiometer) sensor data. MODIS, due to its wider swath, offers more samples than does AATSR. A minimum aerosol optical depth of 0.05 was adopted to ensure retrieval reliability. Further details of these data are summarized in Table 3. Similarly, monthly averaged output from different global aerosol models participating in the AeroCom project (Schulz et al., 2006; Kinne et al., 2006) was also analyzed. For N values were derived for levels warmer than the melting level from the indirect effect analysis of Quaas et al. (2009) and monthly averages of τ_f were analyzed for both the pre-industrial (1850) and present day (2005) conditions (Myhre et al., 2013) Model output was re-gridded to the spatial resolution (1° in latitude by 1° in longitude) of the satellite data for subsequent analysis.

The relationships between τ_f and N in global modelling are quite diverse, and on average stronger than suggested by observations. In contrast, the satellite retrievals are more consistent, even though spatial (and temporal) coverage is limited to overcast oceanic regions. For this reason our parameterization is founded on the satellite data, although in the end the relationship we derive ends up being consistent with the modelling given the large model spread.

Values of fine mode optical-depth and cloud droplet population densities, $\{\tau_f, N\}$, retrieved from satellite measurements are presented in Fig. 6 and 7. The MODIS Collection 6 data are presented for the annual average and for the Boreal summer season to allow for comparison with MODIS Collection 5.1 (annual) and AATSR (seasonal). Due to quality control requirements, whereby retrievals are avoided in broken cloud scenes, the displayed data locations represent only a subset of the actually available data for τ_f and N.

Overall the retrievals suggest that there is a relationship between τ_f and N. For instance regions of elevated τ_f over the eastern-boundary currents in the Atlantic, near the Indian sub-continent, west of Japan and between Japan and the Asian mainland also correspond to elevated values of N. The presence of an apparent relationship is consistent with previous work. Andreae (2009), for instance, related local observations of total aerosol optical depth to measurements of cloud-condensation nuclei and then in a second step related values of CCN to N. Some early studies of aerosol radiative forcing also adopted a similar approach (e.g. Boucher and Lohmann, 1995). The correspondence between τ_f and N is not perfect. For example, elevated values of N over the Californian stratocumulus regions (Fig. 6) do not show a commensurately pronounced retrieval of τ_f (7) – although even here variability in the background contribution to fine-mode aerosol may mask relationships. In addition, although the retrievals of τ_f from the different satellite platforms are broadly consistent, but estimates of N are much more variable and show systematic differences across the various products. Retrievals of N based on MODIS Collection 5.1 yield much larger estimates than those based on Collection 6.0, likely as a result of differences in the retrieval (e.g., Table 3).

Geoscientific
Model Development
Discussions

The co-variation between τ_f and N is quantified through a consideration of all of the available data as shown in Fig. 8. To
35 construct this figure retrieved values of N are binned as a function of coincident values of τ_f. Only values of τ_f between 0.05
and 0.25 are considered. Data below 0.05 were rejected due to noise (see also Remer et al., 2005, who indicate that 0.05 is
basically the detection limit of fine mode AOD). Data above 0.25 were also excluded due to insufficient samples. The data of
the joint histograms are statistically analyzed in twenty τ_f bins. Along the median values in each histogram logarithm fits of
the form $N \propto \ln(\tau_f)$ have been constructed and are displayed in Fig. 8. Despite considerable scatter the relationship between
5   N and τ_f is a systematic one: across almost all of the τ_f bins, N increases with τ_f and this increase becomes smaller the larger
τ_f. A logarithmic function captures this behavior and is consistent with understanding that an increase in τ_f is expected to
be associated with a smaller increase in N the larger N (or τ_f) was to begin with. One reason for such behavior is that with
more available cloud condensation nuclei, peak supersaturations reduce leading to a smaller activated fraction (Twomey, 1959;
Ramanathan et al., 2001; Carslaw et al., 2013). Although the exact form of any purported relationship between τ_f and N can
10 be debated, this analysis shows that a logarithmic relationship reasonably represents the data.

This logarithmic relationship forms the basis for representing the Twomey effect in MACv2-SP. The functional form pro-
posed based on the analysis of the satellite data, Fig. 8, gives

$$N = a_N \ln\left(b_N \langle \tau_a \rangle + \langle \tau_{bg} \rangle\right), \tag{11}$$

where $\langle \cdot \rangle$ denotes a vertical average, and $\{a_N, b_N, \tau_g\}$ are parameters. For the fit to MODIS C6, $a_N = 16$, $b_N = 1000$ and
15 $\langle \tau_{bg} \rangle = 1$. Mathematically $\langle \tau_{bg} \rangle \geq 1$ is necessary to regularize the expression. Physically we associate τ_{bg} with a background
contribution to the aerosol optical depth, as even in a pristine atmosphere cloud condensation nuclei are produced from purely
natural processes. Based on Eq. 11

$$\frac{N(x,y,t)}{N_{1850}(x,y,t_f)} = \frac{\ln\left(a_N + b_N \int_0^\infty (\tau_a(x,y,z,t,550\,[\text{nm}]) + \tau_{bg}(\text{x},\text{y},\text{z},\text{t}_f,550\,[\text{nm}]))\,\text{dz}\right)}{\ln\left(a_N + b_N \int_0^\infty \tau_{bg}(x,y,z,t_f,550\,[\text{nm}])\,\text{dz}\right)}. \tag{12}$$

By prescribing the Twomey effect in the form of the ratio N/N_{1850} the MACv2-SP Twomey effect does not interfere with the
20 background droplet population, N_{1850} of the host model, and it ensures that, all else being equal, the proportional change in N
due to the anthropogenic aerosol will be insensitive to N_{1850}.

In MACv2-SP, τ_{bg}, is calculated identically to τ_a except that there is no emission weighting and the background plume
amplitudes (the τ_i^* in Eq. 4) are chosen to represent the contribution of the pre-1850 aerosol to N_{1850}. Presently these were
chosen to be prescribed factors for industrial versus biomass regions with values that gave what are believed to be reasonable
25 globally and annually averaged droplet concentrations for the present day. A globally uniform background is also included to
represent the effect of distributed sources such as sea-salt, or DMS emissions, on the background droplet population density.
Because it describes the background, τ_{bg} is not emission weighted, but adopts values that are fixed in time. In Eq. (12) the
possibility of maintaining an annual cycle in the prescription of N_{1850} is indicated by the dependence on t_f, even if in the
present implementation of MACv2-SP such an effect is currently not implemented. Because $\langle \tau_{bg} \rangle$ is specified as part of
30 MACv2-SP, it will not necessarily be consistent with the N_{1850} of the models. But given that the purpose is simply to specify a
consistent value of N/N_{1850} for all of the models, this is only a formal inconsistency in how one interprets Eq. 12. Its ultimate

consequence is that it inhibits models with a cleaner background state from having a larger Twomey effect for the same aerosol perturbation.

Equation (12) is consistent with the data and with understanding, but it is admittedly crude. One could imagine a variety of other relationships fitting the data equally well. Precisely for this reason we favor a very simple form, as it makes the underlying assumptions transparent and easy to change. Toward this end, in a companion manuscript, Fiedler et al. (2016) examine in some detail how the effective radiative forcing depends on the form of Eq. (12) and its parameters. Consistent with what was found by

5 Carslaw et al. (2013) it is shown that the strength of the background, τ_{bg}, has the greatest impact on the radiative forcing from aerosol-cloud interactions, and it does so by effectively controlling how far from the plume center aerosol perturbations are allowed to influence cloud properties. If aerosol perturbations are allowed to extend further over the remote oceans, effecting larger regions with darker backgrounds, a greater (more negative) global-mean radiative forcing arises.

4 Assessing the distribution and forcing from MACv2-SP

10 ### 4.1 Aerosol optical depth and cloud active properties climatology

The Simple Plume approach appears to do an adequate job in capturing the main features of the MACv2 climatology of the anthropogenic aerosol. This is illustrated in Fig. 9 where we compare two months of the MACv2 climatology with MACv2-SP. The Simple Plume approach allows for a reasonable fit to the main centers of action over North and South America, Asia, central Africa and Northern Australia, as well as the more complex structure of the aerosol over South and East Asia,

15 extending over the Maritime Continent. The seasonal shift between March where the Asian aerosol is more extended over the Pacific, to September where Southern Hemisphere and Equatorial biomass burning regions are more pronounced is also well captured by the model. As compared to Fig. 2, the treatment of the vertical distribution also helps capture the reduction in column anthropogenic aerosol burden in regions of elevated terrain. This is most evident over the Tibetan Plateau but is also apparent over the Altiplano, near Bolivia, and to a lesser extent over the Alps. Compared to MACv2, the Simple Plume

20 has a somewhat more compact spatial footprint, with somewhat less column burden of anthropogenic aerosol in the southern hemisphere, and the structure of the main aerosol plumes is somewhat smoother reflecting the shape of the underlying plumes. This smoothness causes a somewhat greater eastward extent, for instance, of the Asian aerosol. These types of biases may exaggerate the downstream effect of the cloud active aerosol as they will project effectively onto maritime clouds and the aerosol becomes more radiatively important when extending over a dark surface, like the ocean.

25 To more quantitatively estimate how well MACv2-SP represents present understanding of the present-day anthropogenic aerosol distribution we calculate some global measures and compare them to the spread across state-of-the-art aerosol climate models participating in the AeroCom project. In Table 4 we summarize the global and hemispheric total column aerosol optical depths in MACv2-SP, and the anthropogenic component. MACv2 is well within the range of the AeroCom models, with an aerosol optical depth midway between the AeroCom median model and the lower quartile of the AeroCom model

30 distribution, but a slightly larger anthropogenic component. The hemispheric asymmetry in MACv2 is near, but slightly larger than the AeroCOM median, but well within the inter-quartile spread of the models. The spread across the AeroCom model

spatial distributions, as measured by the root-mean-square difference from the AeroCom mean, is very much larger than the root-mean-square distance between MACv2 and MACv2-SP. The smallest root-mean-square distance of any of the AeroCom models is 0.031, more than 50% greater than the mean distance between MACv2-SP and MACv2. Based on these statistics MACv2-SP lies well within the space of aerosol distributions provided by comprehensive models, and is a good fit to MACv2. This is the basis for our claim that MACv2-SP provides an adequate representation of the anthropogenic aerosol.

The parameterized impact of the anthropogenic aerosol on the droplet population density, results in a little less than 10 % increase in N. In the vicinity of pollution sources the effect can be much larger. Fig. 10 illustrates the annually averaged effect, which is concentrated over the main industrial plumes. Regionally, this can lead to an annual mean increase in droplet population densities by over 35 %. The global mean change in N, assuming clouds are equally likely everywhere, is a little over 7 %. Droplet population density increases by roughly twice this value, 15%, were assumed by Charlson et al. (1992). A globally averaged anthropogenic increase of about 10 % seem reasonable. As a reference, the massive aerosol infusions associated with the Bárðarbunga eruption of 2014, which lead to local aerosol optical depths perturbations of 0.2, resulted in no more than a 50 % increase in droplet population densities (Haywood et al., 2016). Likewise local droplet perturbations in very large aerosol perturbations associated with ship-tracks (Christensen and Stephens, 2011) are found to be of a similar magnitude, and new research (e.g., Kirkby et al., 2016) has has identified pathways to new particle formation through biogenic precursors, thus lessening the dependance of cloud-active aerosol on human related SO_2 perturbations. Stevens (2015) argued that a global change of 15 % is a reasonable upper bound when one considers evidence from ship-tracks. Because MACv2-SP does not interact with the meteorology, a smaller perturbation is required to capture the same radiative effect if the covariance between the aerosol perturbation and cloudiness is negative. Based on these arguments we believe that the changes in droplet population densities parameterized by MACv2-SP are a reasonable representation of the radiative effect associated with the anthropogenic aerosol. Nonetheless, given a poor understanding of the relationship between droplet population densities and bulk properties of the ambient aerosol, this number comes with considerable uncertainty. One advantage of MACv2-SP is the ease with which this uncertainty can be sampled, as is explored further in a companion study by Fiedler et al. (2016).

4.2 Structure and estimates of radiative forcing from MACv2-SP

To give an idea of how much forcing is actually associated with MACv2-SP and to test its implementation within an Earth System Model, we have made estimates of the radiative forcing associated MACv2-SP using the Max Planck Institute Earth System Model (MPI-ESM Giorgetta et al., 2013; Stevens et al., 2013) using an updated atmosphere component, ECHAM6.3, which will be used in the new version (1.2) of this model. AMIP (Atmosphere Model Intercomparison Project) type runs were used for this analysis. The radiative forcing has been calculated from these runs in two different ways. Instantaneous radiative forcing is estimated from an AMIP run through two calls to the radiation, at each radiation timestep. In one call the radiative properties correspond to the given atmospheric state and the pre-industrial (control run) aerosol, and in a second call the pre-industrial aerosol and assumed cloud droplet population density are augmented by the anthropogenic perturbation provided by MACv2-SP. The model feels the radiative heating rates calculated in the second call. A period of 11 years is simulated with sea-surface temperatures, sea-ice concentrations prescribed with values corresponding to the period between 2000 and 2010.

Geoscientific
Model Development
Discussions

To exclude possible effects of the initial conditions the first year was excluded from the analysis. Hence the model samples a variety of climate states over the subsequent ten years. Each of the eleven simulated years has the same annual cycle of anthropogenic aerosol properties. We also calculate the Effective Radiative Forcing, ERF, by comparing an ensemble of three AMIP simulations for the 2000-2011 period using the 2005 MACv2-SP anthropogenic aerosol added to an 1850 (pre-industrial) background aerosol with an ensemble of five simulations for the same period using just this background aerosol. The difference between the instantaneous and effective radiative forcing gives an estimate of the atmospheric adjustments (Sherwood et al.,

5 2015).

The clear-sky ERF is estimated at $-0.8\,\mathrm{W\,m^{-2}}$ and its spatial pattern, shown in the upper panel of Fig. 11 is what one expects given the distribution of MACv2-SP aerosol optical depth, cf. Fig. 9. To estimate how natural variability contributes to uncertainty in the estimate of the ERF we have compared the standard deviation in reflected short-wave radiation for an eleven year period across a one-hundred member ensemble (Stevens, 2015) of our coupled Earth System Model. This amounts to a

10 value of about $-0.08\,\mathrm{W\,m^{-2}}$ suggesting that for a three member ensemble the two-sigma uncertainty in the ERF estimates are about $-0.09\,\mathrm{W\,m^{-2}}$. This estimate of the uncertainty is consistent with the spread across individual ensemble members, and is somewhat less for the clear-sky estimates. Given that the global and annually averaged anthropogenic aerosol optical depth in MACv2-SP is 0.027, a clear-sky ERF of -0.79 corresponds to a radiative efficiency of $-29\,\mathrm{Wm^{-2}}$ per unit optical depth. In a comparison of sixteen state-of-the-art chemistry climate models Myhre et al. (2013) calculate a median radiative efficiency

15 of $-24\,\mathrm{Wm^{-2}}$, and excluding one obvious outlier, the most negative radiative efficiency among the models is $-27.4\,\mathrm{W\,m^{-2}}$.

Brightening the background clouds reduce the clear-sky ERF by about a factor of two from what it would be if there were not clouds. This is illustrated by comparing the clear-sky ERF ($-0.8\,\mathrm{W\,m^{-2}}$) to the all-sky ERF in a simulation in which aerosol-cloud interactions are neglected. The middle panel of Fig. 11 presents the result of this calculation. Without aerosol-cloud interactions the all-sky ERF is about $-0.37\,\mathrm{W\,m^{-2}}$. We call this effect of clouds a cloud-masking as they mask the radiative

20 effect from changes to the clear-sky aerosol, even in cases where the clear-sky aerosol is above the cloud. The simulations yield a cloud masking factor of 0.5. In the AeroCom Phase II models analyzed by Myhre et al. (2013) the median cloud masking factor is 0.37, with considerable scatter among models. Taken together, the somewhat reduced cloud masking and the somewhat higher radiative efficiency, the MACv2-SP implementation of the anthropogenic aerosol in the MPI-ESM gives an all-sky radiative forcing from aerosol-radiation-interactions that is considerably more negative ($-14\,\mathrm{Wm^{-2}}$ versus $-9\,\mathrm{Wm^{-2}}$

25) than the median AeroCom Phase unit optical depth.

Part of the damping of aerosol-radiation-interactions by clouds, is offset when clouds are allowed to be influenced by the aerosol. Including the cloud effects parameterized by MACv2-SP increases the magnitude of the ERF to $-0.685\,\mathrm{W\,m^{-2}}$ so that overall clouds contribute to a small reduction in the magnitude of the ERF over what one would calculate were there no clouds in the atmosphere. In a companion paper (Fiedler et al., 2016) explore the degree to which aerosol-cloud interactions offset the

30 cloud-masking effect on aerosol-radiation interactions and show that this depends primarily on how pristine one assumes the background atmosphere to be.

Differences between the ERF and IRF suggest that changes in the system act to amplify the forcing by about 15%. Double radiation calls yield very stable estimates of the IRF in our model, with a pattern that looks even more similar to the distribution

of the aerosol than does the clear-sky ERF. This is illustrated in the left panel of Fig. 12. The figure also illustrates that the IRF is somewhat less negative than the all-sky ERF. The pattern of adjustments show that the pattern of forcing is mostly amplified by the brightening of the southern hemisphere. This occurs most prominently through remote effects associated with a shift in the intertropical convergence zone over the Atlantic and more reflected shortwave radiation over Australia. Over the regions where the anthropogenic aerosol burden is largest, for instance over central Africa, Europe and East Asia the adjustments actually

5   offset some of the forcing locally. The effect of the adjustments slightly reduces asymmetries in the hemispheric forcing. The ratio of Northern Hemisphere to Southern Hemisphere IRF is about 5.2, whereas for ERF it is only 2.7. It will be interesting to see if other models forced with the same, MACv2-SP, aerosol produce similar patterns of adjustments.

5   Time-varying Forcing

The year to year variations are specified as a time series, $E_i(t_{\mathrm{y}})$ with t_{y} denoting the year following a gregorian calendar.

10 Physically it can be thought of as the column anthropogenic-aerosol optical depth of the ith plume, at the plume center, normalized by its value in a reference year.

$$E_i(t_{\mathrm{y}}) = \langle \tau_i(t_{\mathrm{y}}) \rangle / \langle \tau_i^* \rangle, \tag{13}$$

where angle brackets denote the column integral. By definition $E_i(t_{\mathrm{y}})$ is unity at the reference time, which in the present implementation is the year 2005.

15   Different approaches to the annual scaling have been considered. One approach is to scale values of τ_i by its ratio in any given year to its ratio in 2005 as calculated by aerosol-climate models. This approach can also be readily extended to the future. This connection to the more comprehensive modelling is attractive, but makes the simple plume climatology dependent on an individual model, or models, whose temporal evolution in aerosol forcing is known to differ considerably. Tying E to comprehensive modelling also has the disadvantage that it makes it difficult for individual users to change, or to trace as the

20 required output from models whose methods are (almost by definition) not transparent, nor readily available and updated. For these reasons we choose to adopt a different approach, wherein $E_i(t_{\mathrm{y}})$ is related to estimates of past or projections of future emissions. If $e_{ik}(t_{\mathrm{y}})$ denotes the annual emissions of component k for plume i then

$$E_i(t_{\mathrm{y}}) = \frac{\sum_k w_k \left(e_{ik}(t_{\mathrm{y}}) - e_{ik}(1850) \right)}{\sum_k w_k \left(e_{ik}(2005) - e_{ik}(1850) \right)}, \quad \text{for} \quad t \geq 1850, \tag{14}$$

where w_k denotes the weighting of the k'th constituent to the plume. Defining $e_k(t_{\mathrm{y}})$ as the global emissions of constituent k

25 then the global weighting, $E(t_{\mathrm{y}})$, is defined analogously to Eq. (14). Eq. (14) ensures that $E_i(1850) = 0$ and $E_i(2005) = 1$. This prescription has been chosen with application to the sixth phase of the coupled model intercomparison project (CMIP6 Eyring et al., 2016) in mind, as it allows τ_{a} to be added to the background used by models, traditionally 1850, in their control run. Hence the application of the simple-plume climatology does not require models to rerun their control simulations. If one is interested in using this method for periods prior to 1850, or for scenarios where $e_{ik}(t_{\mathrm{y}}) < e_{ik}(1850)$, then this prescription

30 of $E(t_{\mathrm{y}})$ may have to be revisited. Because a negative perturbation would not be unreasonable, as long as it does not exceed the background, the approach may work even outside of its intended domain of application.

Geoscientific
Model Development
Discussions

The plume amplitudes are scaled to a linear combination of the SO_2 and NH_3 emissions as provided by the Community Emissions Data System (Hoesly, R. et al.,2016 in preparation for submission to GMD CMIP6 special issue). The CEDS is a data-driven open source framework developed to provide historical emission estimates of aerosol and precursor compounds. These emission data are being released for use as historical forcing input data for CMIP6. So as to capture all emissions, each country in the CEDS is associated with one of our nine plumes, as described by Table 7. The $E_i(t_y)$ are provided as an eleven-year averaged value centered at the whole year, yearly values could easily be provided, but specifying the data in terms of decadal averages makes the climatology easier to change. So for instance $E_i(t_{1950})$ is calculated using the emission data from 1945 through 1955 inclusive. Yearly values are then interpolated from these decadal values. Because the CEDS only includes emissions through 2014, the last decadal value in 2010 is an average over the ten year period between 2005 and 2014.

Determining the E_i by SO_2 emissions alone is not the same as assuming that only SO_2 contributes to the anthropogenic aerosol, but rather that other anthropogenic aerosol and precursor compound emissions scale with the emission of SO_2, an important but subtle distinction. This assumption is probably reasonable for the period prior to the late 1970s, after which regulations on SO_2 emissions lead to large decreases in emissions over North America and Europe with less change in NH_3 emissions. Scaling anthropogenic aerosol forcing by SO_2 emissions alone appears to reasonably capture the behavior of CMIP5 models (Stevens, 2015). Nonetheless, there is some evidence that aerosol forcing may have begun to decouple from SO_2 emissions with the onset of more stringent air-quality controls in some countries beginning in the late 1970s and will increasingly do so in the future (Bellouin et al., 2011). To allow for this possibility we add a second component which scales like the NH_3 emissions. The relative weight of these two components is chosen so that the optical depth of the plume associated with the NH_3 component is one third of that from SO_2 (Table 5). This ratio of one third was chosen to match the ratio between present day sulfate and nitrate forcing in the AeroCom II models (Myhre et al., 2013).

As intended, the addition of an NH_3 component to the temporal scaling moderates the effect of air quality regulations since the late 1970s. This is shown in Fig. 13. The blue dashed curve in the upper panel describes the relative contribution of aerosol precursors which scale like SO_2. A value of 0.5, as is for instance evident around 1950 means that these precursors contributed to a global anthropogenic aerosol optical depth relative to 1850 that is 50 % of what it was in 2005. The green dashed curve shows the same for components that scale with NH_3 emissions, and together the blue and green curves sum to $E(t_y)$ as shown by the black curve. Absolute values of the equivalent SO_2 emissions, measured in Mt SO_2 emissions plus 0.55 times NH_3 emissions, and the relative contribution of absorbing aerosol emissions are tabulated for different time periods for the different plumes in Table 6.

The emission-based scaling of the individual plumes also captures the very large regional shifts in aerosol loading over the last forty years. Prior to the 1990s emissions from North America and Europe dominated contributions to the anthropogenic aerosol. Thereafter Asian sources became more important. This is shown in the lower panel of Fig. 13, where here the relative contributions to E from a particular plume, E_i, or a group of plumes, is plotted. It shows, for instance, that in the year 2010 South and East Asia were responsible for 60 % of the total anthropogenic aerosol. Before 1970 emissions in the Atlantic sector were responsible for the vast majority of emissions. Changes in emissions over Europe rather than North America appear to be more important for the rapid rise of emissions, from about half their present day values in 1950 to their local maximum

around 1980. Because European emissions are more centered over the continent, one would expect this rise to be somewhat

35   less effective than it would have been had it been associated with North American sources. The emissions history also suggests that the overwhelming amount of emissions have and continue to be dominated by Northern Hemispheric sources.

In the present implementation, the single-scattering albedo of the individual plumes does not vary with time. A different balance of emissions of absorbing versus scattering aerosols can be evaluated by comparing estimates of historical black carbon emissions to the emission factors used to scale the amplitudes of the MACv2-SP plumes. This ratio is plotted in Fig. 14,

5   and suggests that the ratio was more or less constant over the first half of the last century, and began to decrease after around 1980 as efforts were made to limit SO_2 emissions. A more absorbing anthropogenic aerosol would, all else being equal, lead to less radiative forcing per unit optical depth. On the global scale the effects are not large. On regional scales the effects are larger, as is demonstrated by comparing the change in the ratio of black carbon to equivalent SO_2 emissions over the historical record (e.g., Table 6). Based on the CEDS data the amount of black carbon emissions per unit equivalent SO_2 emissions was about

10   twice as large in 1950 as it was in 2005. This brightening of the aerosol prior to about 1970 suggests that aerosol forcing in the period before extensive efforts to reduce SO_2 emissions in the 1970s would have made the early century forcing progressively more potent, with increased emissions less potent (as measured at the top of the atmosphere) after 1980. For the present such effects are not included in MACv2-SP, which does not consider aerosol composition changes for biomass and industrial plumes over time, but experiments to judge the magnitude of such changes are warranted.

15   ## 6   Conclusions

An empirical analytic parameterization of anthropogenic (post 1850) aerosol optical properties and their associated Twomey-effect has been developed for use in climate modelling studies. The climatology is empirical in that it is fit to the gridded MACv2 climatology, and thereby is directly constrained by understanding and measurements of the spatial distribution of the present-day anthropogenic aerosol. An analytic description was motivated by a desire to ease implementation and input

20   data requirements, thereby helping ensure that the climatology could be consistently implemented across a range of models, including very high-resolution models. A description of the aerosol in terms of radiative, and cloud-active, properties was motivated by a desire to have allow a consistent implementation across models. By describing the aerosol in terms of the post 1850 anthropogenic perturbation we also avoided the problem of perturbing the control climate of models that may wish to adopt our approach. The motivation for constructing a plausible representation of the anthropogenic aerosol that could be

25   consistently implemented in many climate models was the hope that a consistent response to a consistent forcing across many models would provide a stronger top-down constraint on the magnitude of that forcing.

It is demonstrated that a plume-based model, which we call MACv2-SP, with relatively few degrees of freedom adequately captures the more complex MACv2 grid-point climatology. Nine plumes, describing the patterns of aerosol loading attributable to major emission regions, were sufficient to capture spatial variations in the anthropogenic aerosol. Each plume is in turn con-

30   structed from two independent features designed to capture differences in the near and far field aerosol response to sources, and differences in meteorology that shape the plumes. Account was also taken of the annual cycle, the vertical distribution, and the

spectral dependence of aerosol optical properties. Perturbations to cloud active properties associated with the anthropogenic aerosol were scaled by aerosol optical depth, using relationships derived from observational data and more comprehensive modelling. Despite its vastly reduced number of degrees of freedom, MACv2-SP is capable of reproducing the spatial distribution and amplitude of the aerosol optical depth in MACv2, fitting the observations much better (RMSE of 0.19 versus an AeroCAeroCom median RMSE of 0.63) than what is presently possible using process-based models. Other features such as total aerosol optical depth and the ratio of Northern Hemisphere to Southern Hemisphere loading is also well captured by

5   MACv2-SP.

MACv2-SP represents temporal variations in the anthropogenic aerosol by scaling the strength of its plumes in the year 2005 by estimates of historic (or possibly projections of future) emissions. In deriving the temporal scaling, both nitrate-like and sulfate-like aerosol precursors are accounted for. By 'nitrate-like' or 'sulfate-like' we mean that the temporal scaling of the precursors is like nitrate or like sulfate, but could in reality be attributable to a broader range of anthropogenic aerosol sources.

10   These scaling factors are derived by associating national emission inventories with the nine plumes and provide a simple way of linking knowledge of aerosol emissions to plausible patterns of radiative forcing.

MACv2-SP is implemented into the Earth System Model of the Max Planck Institute for Meteorology (the MPI-ESM v1.2), and an ensemble of simulations is used to estimate instantaneous and effective radiative forcing. Both forcing estimates for clear and all-sky are calculated. The effective radiative forcing is estimated from the simulations to be $-0.7\,\mathrm{W\,m^{-2}}$. Clouds, by

15   masking aerosol-radiation interactions, diminish the forcing, something that is partially offset by accounting for aerosol-cloud interactions. As a result the net effect of clouds on aerosol radiative forcing is small, but slightly positive, i.e., the clear-sky effective radiative forcing is more negative $-0.8\,\mathrm{W\,m^{-2}}$. Because cloud masking effects are not independent of the aerosol-cloud interactions, the effect of clouds, which here are small, can be inflated if the two effects are considered independently An instantaneous radiative forcing of $-0.6\,\mathrm{W\,m^{-2}}$ is associated with the MPI-ESM v1.2 implementation of MACv2-SP, as

20   estimated from a double call to radiation. Adjustments, defined as the difference between the effective and instantaneous radiative forcing thus act to strengthen the overall forcing by 15 % to 20 %.

The forcing estimates are in line with previous estimates. Nonetheless, the somewhat stronger radiative efficiency, of $-29\,\mathrm{W\,m^{-2}}$ versus $-25\,\mathrm{W\,m^{-2}}$ in earlier studies, suggests that the clear sky effects may be too large in magnitude. This may be due to a too large single-scattering albedo, or a too oceanic extent of the plumes, as the MACv2 climatology is mostly

25   constrained by land-based measurements.

Though an effort has been made to characterize different measures of the radiative forcing associated with the MPI-ESM v1.2 implementation of MACv2-SP, these numbers should be taken with a grain of salt. The real purpose behind the development of MACv2-SP is to enable its use across a range of models in the hope that robust model responses emerge in a way that helps provide more fundamental constraints on the forcing, for instance through detection and attribution approaches. Such an effort

30   would be aided if MACv2-SP is adopted for use by other models.

7 Data and code availability

The MAC-v2-SP climatology, including algorithms and input data used to generate the climatology are provided as an electronic supplement to this manuscript. Primary data and scripts used in the analysis and other supplementary information that may be useful in reproducing the author's work are archived by the Max Planck Institute for Meteorology and can be obtained by contacting publications@mpimet.mpg.de.

Author contributions. BS conceived the simple plume model, implemented it based on a prototype developed by the whole team and wrote the manuscript. SF helped with the implementation and tuning of the model and contributed to the writing of the manuscript. SF, BS and TM designed and evaluated the ECHAM experiments which were performed by TM and SF. SK led the development of the underlying MACv2 climatology, performed the offline radiative calculations, advised on the design of the plume model, and together with JM, BS and SF designed the cloud active component. JM performed the analysis of the AERCOM-II models and climatological data-sets of droplet number. KP and SR designed the plume model, contributed text describing its formulation, and provided the initial tuning of this model. The authors declare that they have no conflict of interest

Figure 5. Variation of the column and globally averaged anthropogenic aerosol optical depth over the annual cycle. Shown are values for the year 2005 for the global average (solid) and for the deep, equatorward of $15°$, tropics (dashed).

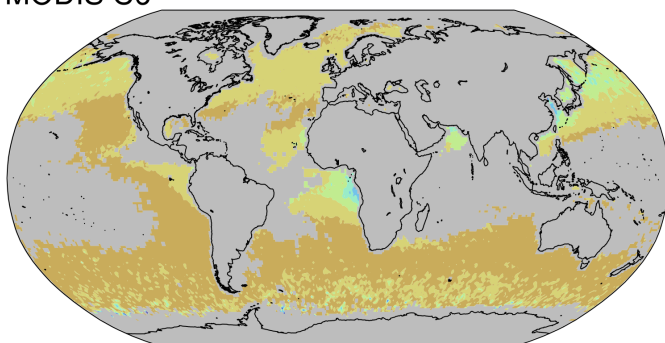

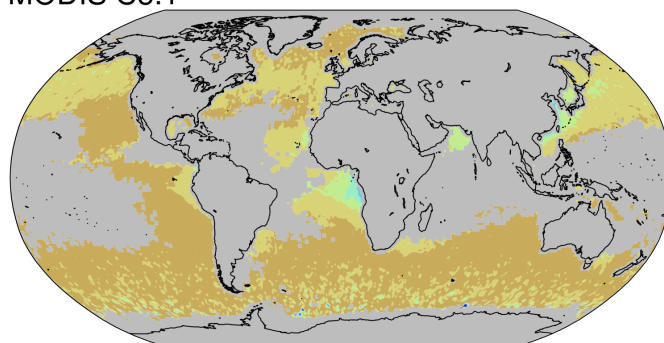

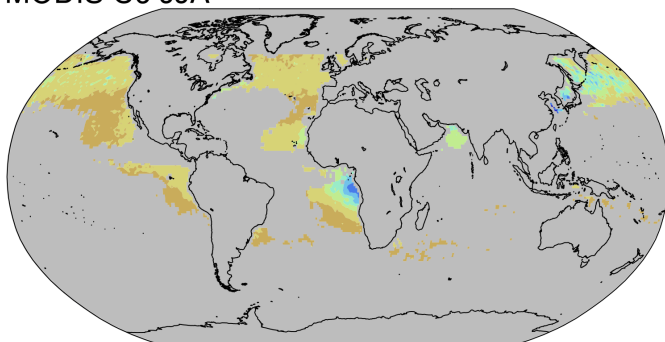

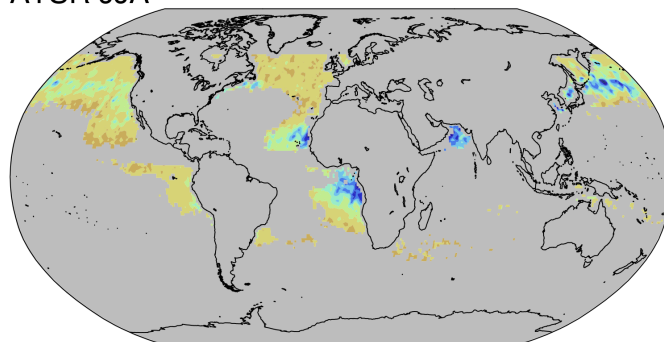

Figure 6. Fine-mode aerosol optical depth (at 550 nm) from different satellite retrievals. Shown are annual averages of MODIS collection 6 for 2008 (upper left), MODIS collection 5.1 for 2007 (upper right); boreal summer (JJA) 2008 averages of MODIS collection 6 (lower left) and boreal summer (JJA) for AATSR-ORAC (lower right)
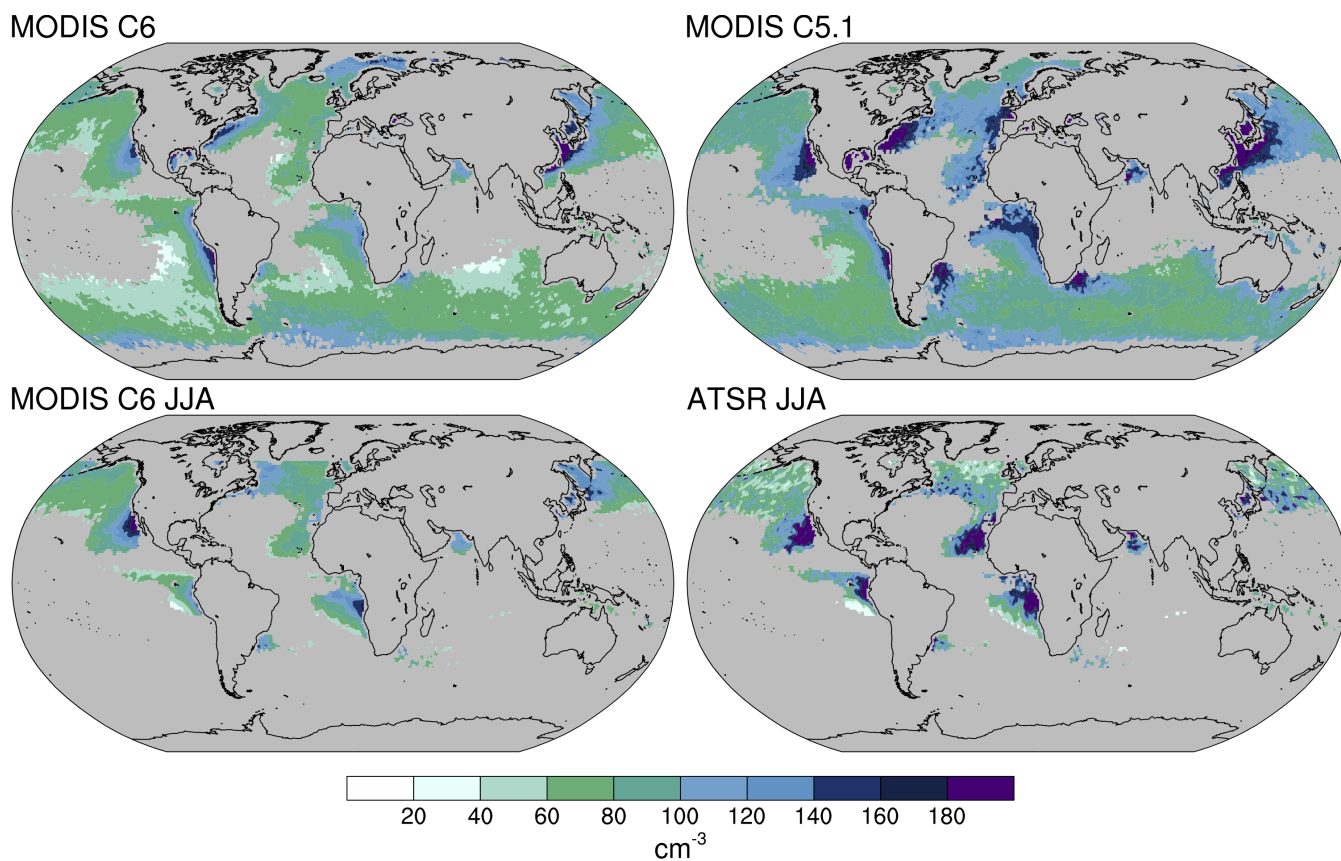

Figure 7. Annual averages N from different satellite retrievals. Shown are MODIS collection 6 for 2008 (upper left); MODIS collection 5.1 for 2007 (upper right); boreal summer (JJA) 2008 averages of MODIS collection 6 (lower left) and boreal summer (JJA) for AATSR-ORAC (lower right)
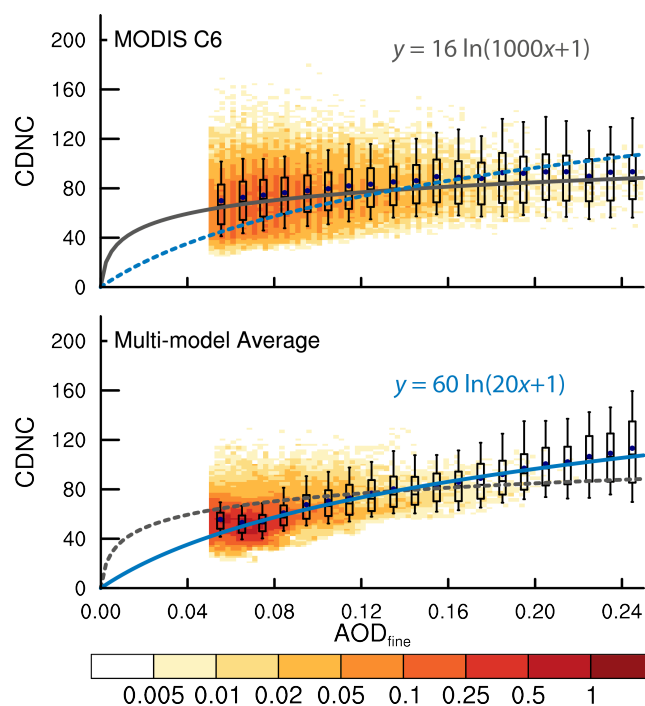

Figure 8. Fine-mode aerosol optical depth and cloud droplet population density joint histograms based on monthly ($1 \times 1°$) averaged data. Histograms based on retrievals from MODIS collection 6 (upper left) and MODIS collection 5.1 (upper right) for an entire year as well as for JJA only data of MODIS collection 6 (lower left) and of AATSR-ORAC (lower right). The derived relationship is presented in the upper right section of each panel based on a fit along the highest frequency of 20 AOD section bins. The data in each AOD are summarized by boxes, which indicate the 25th and 75th percentiles. The whiskers outside each box indicate the 10th and 90th percentiles, the horizontal line and the dot in each box indicate the median and average, respectively.
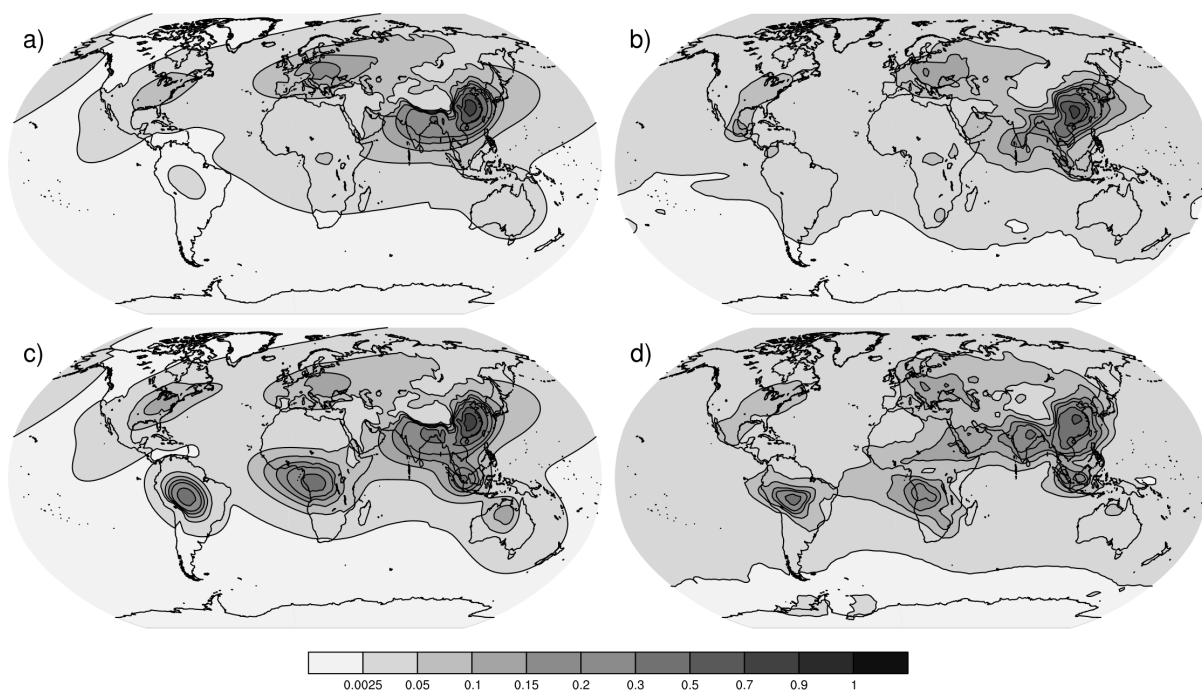

Figure 9. Column anthropogenic aerosol optical depth for March and September, from MACv2-SP and MACv2. Anthropogenic column aerosol optical depth for March from MACv2-SP, panel a; and MAC-v2, panel b; and for September from MACv2-SP, panel c; and for MAC-v2, panel d. Note the distortion of the scale to better illustrate very high and low optical depths.

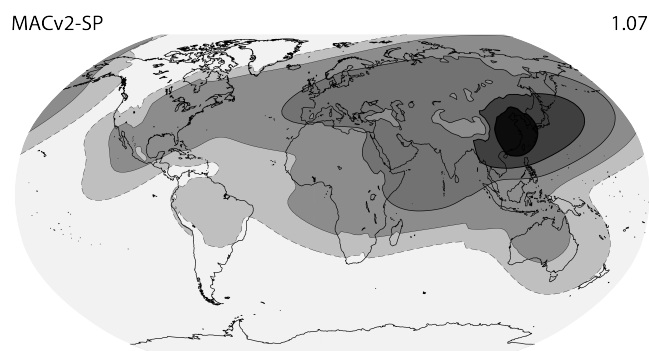

Figure 10. Proportional change in cloud droplet population density associated with anthropogenic aerosol. Contours levels denote a 2 (dashed), 7, 15, 25 and 35 % (thickened) increase in population density. The globally averaged ratio is given on the upper right.

Figure 13. Contributions to AOD distribution. The annual scale factor for the global emissions, $E(t_y)$ shows the strength of the globally averaged post 1850 anthropogenic AOD relative to its value in 2005, along with the relative weighting of its precursors which scale with SO_2 versus NH_3 emissions respectively, panel (a). Regional contributions (panel b) showing the contributions from the $E_i(t_y)$ of different regions to $E(t_y)$. Four regions are shown: Europe (blue), North America (grey), South and East Asia (red), and the four biomass plumes (black). Eleven year averages centered at the start of each decade are shown by filled circles. The departure between the circles and the lines for the Asian plumes in 1850 is because emissions over E. Asia actually decreased in the first decade after 1850, and the decadal scaling coefficients were not allowed to be negative.
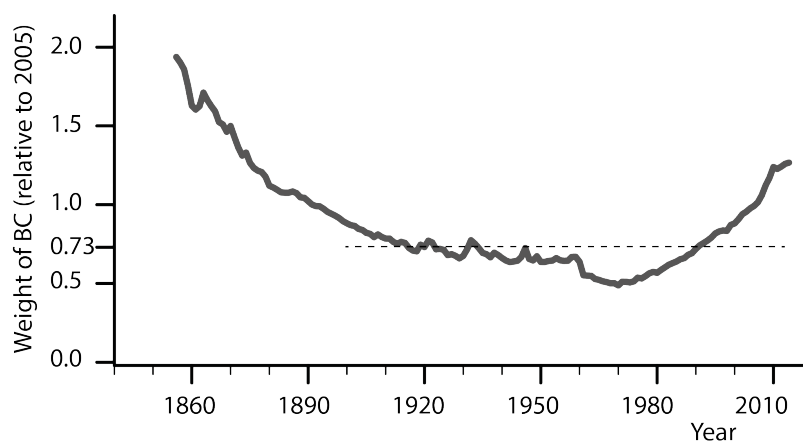

Figure 14. Relative weight of black carbon emissions versus equivalent SO_2 emissions as compared to a value of unity in 2005. A value of 0.75 in 1920 implies that the emissions of black carbon relative to the weighted SO_2 and NH_3 emissions were 75% of their 2005 value. The dashed line, corresponding to a ratio of 0.75, is the mean from 1900 to the present.

Table 1. Annual cycles for individual plumes. Plumes which have a non-harmonic contribution to their annual cycle have larger amplitude (90-100%) annual variations.

#	Source Region	Lat	Lon	Type	Main features of annual cycle
1	Europe	49.4	20.6	Industrial	Amplitude 25%, May max
2	North America	40.1	277.5	Industrial	Amplitude 30%, July max
3	East Asia	30.0	114	Industrial	Amplitude 15%, biharmonic, Oct and Apr max
4	South Asia	23.3	88.0	Industrial	Amplitude 10%, maximum in mid July
5	North-Africa	3.5	22.5	Biomass	Non-harmonic, Dec max, Mar-Oct min
6	South America	-10.3	298.0	Biomass	Non-harmonic, Sep max, Jan-Jun min
7	Maritime Continent	-1.0	106.0	Biomass	Non-harmonic, Sep max, Jan-Jun min
8	South-Central Africa	-3.5	16.0	Biomass	Non-harmonic, Aug max, Jan-Dec min
9	Australia	-20.0	135.0	Industrial	Amplitude 60%, Sep max

Table 2. Optical properties as a function of plume type. Here $\omega_{i,550}$ denotes the single scattering albedo at 550 nm, $\gamma_{i,550}$ the asymmetry parameter at 550 nm and α the angstrom coefficient in Eq. (1).

Plume Type	$\omega_{i,550}$	$\gamma_{i,550}$	α
Industrial	0.93	0.63	2.0
Biomass	0.87	0.63	2.0

ISO codes for countries contributing to different plumes

Table 3. Satellite data used to evaluate the relationship between fine-mode optical depth and cloud-droplet population density.

Platform	Description
MODIS-Collection 5.1	Level 3 data from NASA's EOS-Aqua platform for the 12 months from December 2006 to November 2007. Retrievals of cloud droplet population densities, N, assume that they are constant throughout the cloud and that the liquid water is linearly increasing with height in the cloud. Estimates of N are derived using the multi-spectral method (Nakajima et al., 1991) by combining simultaneous retrievals of both cloud optical depth and droplet radius at the cloud top. See (Grosvenor and Wood, 2014) for further details. Corresponding τ_f data taken from NASA's LAADS website
MODIS-Collection 6.0	Level 3 data from NASA's EOS-Aqua platform for the 12 months from January 2008 to December 2008. Estimates of the cloud-droplet population density are based on the assumption of adiabatic stratification (Bennartz, 2007),(Brenguier et al., 2000) and were provided by John Rausch of Vanderbilt University. Corresponding τ_f data were pulled from NASA's LAADS website.
AATSR	Data are from ESA's ENVISAT platform for the three months period (Jun 2008 - Aug 2008). CDNC and τ_f data were retrieved with the Oxford-RAL Aerosol and Cloud (ORAC) retrieval algorithm (Thomas et al., 2011) and data for CDNC and τ_f were provided by Matthew Christensen from the Rutherford Appleton Laboratory).

Table 4. Metrics of column optical depth for the total (anthropogenic and natural) aerosol. Shown are the global values, the hemispheric ratio and the root mean-square difference. For the AeroCom models this is calculated with respect to the AeroCom mean, for MACv2-SP this is calculated relative to MACv2. In the case of the total aerosol, for the AeroCom models we consider 26 calculations and disregard the outliers by showing the values of the first and third quartiles and the median. For the anthropogenic aerosol the tabulated results are taken from Table 2 of Myhre et al. (2013).

Aerosol	Global	NH/SH	RMSE	Anthropogenic
MACv2	0.124	1.99	n/a	0.030
MACv2-SP	0.121	1.93	0.019	0.028
AeroCom Q1	0.116	1.52	0.048	0.026
AeroCom Median	0.131	1.94	0.063	0.027
AeroCom Q3	0.150	2.19	0.071	0.040
