Abstract
The VAMPER permafrost model has been enhanced with snow thickness and active layer calculations in preparation for coupling within the iLOVECLIM earth system model of intermediate complexity. In addition, maps of basal heat flux and lithology were developed within ECBilt, the atmosphere component of iLOVECLIM, so that VAMPER may use spatially varying parameters of geothermal heat flux and porosity values. The enhanced VAMPER model is validated by comparing the simulated modern day extent of permafrost thickness with observations. To perform the simulations, the VAMPER model is forced by iLOVECLIM land surface temperatures. Results show that the simulation which did not include the snow cover option overestimated the present permafrost extent. However, when the snow component is included, the simulated permafrost extent is reduced too much. In analyzing simulated permafrost depths, it was found that most of the modeled thickness values and subsurface temperatures fall within a reasonable range of the corresponding observed values. Discrepancies between simulated and observed are due to lack of captured effects from features such as topography and organic soil layers. In addition, some discrepancy is also due to disequilibrium with the current climate, meaning that some permafrost is a result of colder states and therefore cannot be reproduced accurately with the iLOVECLIM preindustrial forcings.

1 Introduction
The VU Amsterdam Permafrost (VAMPER) model is a deep 1-d heat conduction model with phase change capability. It has been previously validated for single site experiments such as Barrow, Alaska (Kitover et al., 2012). Subsequently, it has simulated both equilibrium and transient permafrost depth estimates at a number of arctic/subarctic locations (Kitover et al., 2012; Kitover et al., 2013). The VAMPER model was built with the intention to couple it within iLOVECLIM, an earth system model of intermediate complexity. Using this coupling, the goal is to capture the transient nature of permafrost growth/decay over millennia as a feedback effect during major periods of climate change. To prepare for coupling, a few enhancements have since been made to the VAMPER model. As a next step, we validate these improvements by simulating modern-day permafrost thickness and distribution. The goal of this paper is to describe the enhancements and then analyze the validation experiments for modeling present-day permafrost, with detailed explanation of why mismatches occur between simulated and observed data.
The first example of VAMPER as a stand-alone deep permafrost model was for Barrow, Alaska (Kitover et al., 2012) where the experiment reproduced the present-day permafrost depth using monthly averaged observation data of ground “surface” (- 1 cm deep) temperatures. In this same study, VAMPER was also validated by comparing results against other developed deep permafrost models (also used for millennial-scale simulations) using similar forcings and parameter settings. In both Kitover et al. (2012) and Kitover et al. (2013), a number of transient simulations at selected locations (e.g. Wyoming, West Siberia, Central Siberia) were performed using the stand-alone version of the VAMPER model, forced by iLOVECLIM-generated land surface temperatures over the last 21k years (Roche et al., 2011). In addition, a sensitivity analysis was presented in Kitover et al. (2013), showing the range of simulated permafrost depths under different parameter settings.

Thus far, according to the work summarized above, VAMPER has only been employed as a site-specific permafrost model. However, the advantage of the model being simple with limited parameterization requirements, hence resulting in speedy computation times, have not been fully realized since it is not yet coupled with iLOVECLIM. As a next step, this paper describes the necessary developments and validation to couple VAMPER with ECBilt, the atmospheric component of iLOVECLIM. Specifically, this presented work introduces two enhancements to the VAMPER model: 1) inclusion of snow as optional layers and 2) change in the timestep. The first in particular is an issue in modeling permafrost since snow cover is a recognized influence on the ground thermal regime (Williams and Smith, 1989) and was not an available option in the previous VAMPER model version. To compensate for this, Kitover et al. (2013) had artificially introduced the effect of snow cover via a surface offset (the difference between the ECBilt land surface temperature and the VAMPER ground surface temperature) of + 2°C. Not only was this an assumption based on a number of previous reports and observations, but it had to be applied as an annual surface offset since the time step was one year. This then demonstrates the need for the other enhancement, which is a sub-annual timestep, where the seasonal changes in the ground thermal conditions can be captured, allowing for representation of both the snow cover effect and the active layer. In addition to the VAMPER model enhancements, two global maps were produced (geo-processed from the original maps to fit the horizontal grid of ECBilt) to be used as additional input parameters to the VAMPER model: geothermal heat flux and porosity. These are particularly used when VAMPER is run over a horizontal grid, in turn allowing the parameters to vary spatially.

Integrating permafrost into earth system models has become of increased interest since research has acknowledged the effect of climate change on permafrost temperatures (Cheng and Wu, 2007), permafrost degradation (Anisimov and Nelson, 1996), and carbon stored within the permafrost (Davidson and Janssens, 1996). The Coupled Model Intercomparison Project phase 5 (Koven et al., 2013) analyzed how different earth system models represent the subsurface thermal dynamics and how well this class of models simulate permafrost and active layer depth. Despite the fact that there is a variety of modeling methods and configurations for the different global coupled models, the conclusion was that there is no clear ranking among the reviewed 15+ model versions. This shows that representing permafrost in earth system models still has some challenges, which Koven et al. (2013) attribute primarily to modeling of both the atmosphere/ground energy exchange and the subsurface thermal regime. Until recently, most simulations of permafrost were calibrated for regional or local
study such as Li and Koike (2003) on the Tibetan Plateau, Zhang et al. (2006) in Canada, and Nicolsky et al. (2009) in Alaska. A growing number of studies are now modeling permafrost across the Northern Hemisphere or globally. Simulations are done using either statistical approaches like the frost index method (Anisimov and Nelson, 1996; Stendel and Christensen, 2002) or climate models such as Dankers et al. (2011) who used the JULES land surface model and Ekici et al. (2014) who used the JSBACH terrestrial ecosystem model. Other examples include Lawrence and Slater (2005), who used the Community Climate System Model (CCSM) to look at future permafrost extent and associated changes in freshwater discharge to the Arctic Ocean. Schaeffer et al. (2011) used a land surface model (SiBCASA) to simulate reduced future permafrost coverage and subsequent magnitude of the carbon feedback. Similarly, Schneider von Deimling et al. (2012) and Koven et al. (2011) also modeled future estimates of carbon emissions due to thawing permafrost. From a paleoclimate perspective, DeConto et al. (2012) used a version of the GENESIS GCM to model the connection between permafrost degradation and subsequent carbon emission as a driver for the occurrence of the Palaeocene–Eocene Thermal Maximum (PETM). Modeling permafrost changes is also an interest from the hydrological perspective. Avis et al. (2011) used a version of the UVic Earth System Climate Model to examine the potential decreasing areal extent of wetlands due to future permafrost thaw.

However, it should be noted that there is a difference between coupled models which actively integrate the role of permafrost (including the thermal, hydrological, and/or carbon feedbacks) (Lawrence et al., 2011), and models which look at permafrost in a post-processing perspective (e.g. Buteau et al., 2004, Ling and Zhang, 2004) meaning they are forced by the predicted temperature changes. It is the full coupling with integrated feedbacks which is of our current interest, where the goal is to fully couple ECBilt and VAMPERS within iLOVECLIM. The results of the work presented here serve as an important validation stage toward this goal. In the sections following, the two enhancements to the VAMPER model are explained. This includes validation of the timestep change by comparing simulated annual active layer depths with empirical-based estimates. Next, two newly developed maps of spatially varying parameters used in the VAMPER experiments are explained. For the validation, the VAMPER model is forced by ECBilt land surface temperatures, where the results are compared against a modern-day map of permafrost extent in the northern hemisphere and observed permafrost thickness and subsurface temperatures values in boreholes.

2 METHODS

2.1 VAMPER model

2.1.1 General Description

VAMPER is a 1-d permafrost model developed to estimate permafrost thickness and is designed for eventual full coupling with iLOVECLIM. Consequently, the representation of the soil and subsurface in VAMPER should fit the spatial space of iLOVECLIM, implying that detailed parameterization schemes are not suitable for VAMPER. VAMPER is meant rather as a generalized model to simulate conceptual permafrost thickness based on the factors which most strongly dictate the subsurface thermal regime.
Most notable for our purposes and discussed by Farouki (1981), these factors are mineral composition, water content, and temperature.

Other than what is specified below, construction of the VAMPER model has not changed and the methods as described in Kitover et al., (2013) still apply. In particular, these include assuming only conductive heat transfer in the subsurface and employing well-established methods for finding the temperature-dependent thermal properties of heat capacity and thermal conductivity (Farouki, 1981; Zhang et al., 2008). The subsurface is assumed to be saturated (i.e. porosity equals the water content) and there is currently no groundwater flow either horizontally or vertically between the soil layers.

The phase change process of freeze/thaw in the subsurface is handled using a modified apparent heat capacity method from Mottaghy and Rath (2006). Their method assumes that phase change occurs continuously over a temperature range, which in our case is approximately between 0 and -2 °C. The apparent heat capacity method includes an additional latent heat term in the heat diffusivity equation as a way to account for the added energy released (consumed) during freeze (thaw) of the subsurface water content. The latent heat demand during phase change, referred to as the ‘zero curtain effect’, slows thermal diffusivity rates near the surface as the active layer freezes and thaws but also during permafrost degradation/aggradation.

2.1.2 VAMPER Model Enhancements

As compared to most permafrost modeling studies, there are few which have reproduced changes in permafrost thickness over geologic time periods. In these cases, they assume a larger timestep in their numerical simulations (usually one month or one year) (e.g., Osterkamp and Gosink, 1991; Lebret et al., 1994; Lunardini, 1995; Delisle, 1998) since they only need to force the models with the low frequency changes in air temperature or ground temperature that occur over millennia. At this timescale, it is not necessary to use a sub-annual timestep. In our earlier work with the VAMPER model (Kitover et al., 2013), we similarly used a yearly timestep. However, in light of the future coupling between ECBilt and VAMPER, it has become clear that the VAMPER model should run on a 4-hr timestep. Doing this allows VAMPER to match the timescale of the atmosphere, the subsystem to which the VAMPER model will be coupled. Changing to a 4-hour timestep also reduces error in the numerical approximation since the change in thermal properties, which are temperature-dependent, is smoother between each timestep. Since the VAMPER model is somewhat simplified, and hence flexible, the change to a 4-hr timestep required revalidating the model performance. In addition to the change in timestep, we also included a snowpack representation in the VAMPER model. Including this option is meant to simulate the effect of thermal insulation of the ground in winter. Note that the VAMPER model with the snow enhancement is referred to as the VAMPER(S) model. When referring to both/either versions, the “VAMPER(S)” term is used.

Timestep
To illustrate the difference between applying the same annual average temperature forcing but with two different timesteps (4-hr vs. yearly), a sensitivity test was performed (Fig. 1a). To generate the sub-daily surface temperature forcing (4 hours), a year-long temperature time-series was calculated using a standard sine function with constant amplitude 20°C and average annual temperature of -6 °C (hereafter referred to as sensitivity run 1 or “sr1”), resulting in an annual range of temperatures between -26 °C and 14°C. The case with a yearly timestep, called “sr2”, used -6 °C as the constant forcing. Besides the change in timestep and corresponding surface temperature forcing, the thermal conductivity and heat capacity values were also allowed to differ since these variables are temperature-dependent (Fig. 1b). However, the lower boundary heat flux and porosity parameter settings were the same in both model runs. Each experiment was run until approximate equilibrium was reached under the same constant (respective) forcing. We consider equilibrium to be when the geothermal heat flux is approximately equal to the ground heat flux (what goes in = what goes out). Comparing the final depth-temperature profiles between sr1 and sr2 shows a shift in the equilibrium depth-temperature profile where using an annual timestep underestimates permafrost thickness by approximately 50 meters (Fig. 1a). This difference is attributed to occurrence of the thermal offset (difference between ground temperature and top of the permafrost) within the active layer in sr1 (Fig. 1b), whereas sr2 cannot exhibit such seasonal phenomena. Since VAMPER is a simple model (absence of vegetation, organics, an unsaturated subsurface, or temporally varying water content) we can attribute the thermal offset to seasonal differences in thermal conductivity, whereas the thermal conductivity of ice is four times that of unfrozen water and therefore the freezing front is propagated more effectively than the warming front. This difference causes the mean annual subsurface temperature within the active layer to be gradually colder with depth. The offset is visible in the mean annual depth-temperature profile within the top meter of Figure 1b.

**Active Layer**

In permafrost modeling, an active layer can only be present when the air/ground temperature forcing varies seasonally. Thus, the timestep must be sub-annual. Since a 4-hr timestep is now implemented, the VAMPER model produces an active layer. It necessary within the framework of model development to then check the simulation of this active layer for validation purposes.

Most dynamical permafrost models that simulate near-surface behavior configure the parameter settings to specifically match locally observed data. Some parameterizations include organic and mineral layer thicknesses, which give soil properties such as porosity and bulk density, and unfrozen water content characteristics. Examples of these site-specific studies include for example, Romanovsky and Osterkamp (2000), Buteau et al. (2004), Ling and Zhang (2004), and Zhang et al. (2008), and Nicolsky et al. (2009). Since VAMPER is not parameterized to capture site-specific behavior, it is challenging to assess the ability of the model to simulate active layer dynamics. Fortunately, there is a calculation called the Stefan equation, used originally in engineering applications (Fox et al., 1992), to estimate the thickness of the active layer when the amount of energy input and thermal characteristics are known. From French (2007), the Stefan equation is defined as

$$AL = \sqrt{2\alpha k_m \over Q_l}$$  (1)
where \( AL \) (m) is the thickness of the active layer, \( \sigma \) is the cumulative thawing index (average ground surface temperature \((^\circ C)\) during the thaw season times the duration of thaw season \((s)\)), and \( k_{mw} \) is the thermal conductivity of unfrozen soil \( (W \text{ m K}^{-1}) \). \( Q_i \) \((J \text{ m}^{-3})\) is defined further as

\[
Q_i = L \rho_m (W - W_u)
\]

where \( L \) is the latent heat of fusion, \( \rho_m \) is the dry density of the soil \((\text{kg m}^{-3})\), \( W \) is the total moisture content, and \( W_u \) is the unfrozen water content. Table 1 gives the constant variable values applied in the Stefan Equation, which are the same values used in a comparable run for the VAMPER model.

Under different forcings as a function of both average annual ground surface temperature and annual amplitude, the VAMPER model’s active layer thickness versus results using the Stefan Equation are shown in Table 2. It is clear when comparing the empirically-based results with the series of simulations, that the VAMPER model does a suitable job of reproducing annual active layer thickness.

**Snowpack parameterization**

An additional option to the VAMPER model is the ability to extend the heat conduction model into the snowpack when present. Prior to this, the surface offset, illustrated in Smith and Riseborough (2002), could not be produced in the VAMPER model.

The VAMPER model uses snow water equivalent \((\text{swe})\) values (m) with corresponding density to compute snow thickness layers. Snow water equivalent is the depth of water that would result from the complete melting of snow. The precipitation simulated in ECBilt is computed from the precipitable water of the first atmospheric layer (Goosse et al., 2010). When the air temperature is below \(0^\circ C\), the precipitation is assumed to be snow. However, this ‘snow’ is only assumed to be frozen water, meaning it lacks any quantifiable properties besides the actual precipitation amount, and as such is directly considered the swe value. As a result, there is an additional set of necessary functions when coupled with VAMPER to transfer ECBilt swe values into a snowpack thickness \((Z)\) at time \(t\):

\[
Z^t = \rho_s \text{swe}^t / \rho_s^t
\]

where \( \rho_w \) is water density and \( \rho_s \) snow density (Lynch-Stieglitz, 1994). The total snow density is determined as a combination of old snow (expressed as \(\text{swe}^{t-1}\) from the previous timestep) and freshly fallen snow at current timestep (expressed as \(\text{swe}^{fr}\)):

\[
\rho_s^t = (\text{swe}^{t-1} \rho_s^{t-1} + \text{swe}^{fr} \rho_{fr}) / \text{swe}^t
\]

\[
\text{swe}^t = \text{swe}^{t-1} + \text{swe}^{fr}
\]

where \( \rho_{fr} \) is the density of fresh snow \((150 \text{ kg m}^{-3})\).

There is snowpack metamorphism that occurs from a number of different processes. Notably, Dingman (2002) distinguishes these as gravitational settling, destructive metamorphism, constructive
metamorphism, and melt. However, as these different changes occur at highly varying rates and under localized conditions (aspect, slope, vegetation cover), it is impossible to incorporate such processes in an Earth System Model of Intermediate Complexity (EMIC) such as iLOVECLIM. On the other hand, a snowpack always undergoes densification over time and this effect should somehow be applied to the modeled snowpack. Therefore, we apply to the total snow density an empirical densification function due to mechanical compaction. The maximum allowable density is 500 kg m\(^{-3}\), which cannot hold any more liquid water (Dingman, 2002). The compaction equation used (e.g. Pitman et al., 1991; Lynch-Stieglitz, 1994;) is as follows:

\[
\rho_s^t = \rho_s^{t-1} + \left( 0.5 \times 10^7 \rho_s^{t-1} g N \exp \left[ 14.643 - \frac{4000}{\min(7+273.16,273.16)} - 0.02 \rho_s^{t-1} \right] \right) \Delta t
\]  

(6)

where \(g\) is gravity (9.82 m s\(^{-2}\)), \(N\) (kg) is the mass of half the snowpack, \(T\) (°C) is the temperature of the snowpack (the average temperature of the snow layer temperatures from the previous timestep), and \(\Delta t\) is the timestep (s).

Three snow layers are then discretized from the total snow thickness, depending on whether it is above or below 0.2 m, as outlined in Lynch-Stieglitz (1994). Thermal properties are then calculated for each snow layer based on empirical formulas:

\[
K_s = 2.9 \rho_s^2
\]

(7)

\[
C_s = 1.9 \times 10^6 \rho_s / \rho_f
\]

(8)

where \(K_s\) is the snow thermal conductivity and \(C_s\) is the snow heat capacity, and \(\rho_f\) is the density of ice (920 kg m\(^{-3}\)). All three snow layers are subject to the same processes and simply depend on temperature, time, and thickness for their respective deformation and/or melting.

The following is a stepped description of the snow algorithm to generate a VAMPERS snowpack from ECBilt precipitation:

1. Calculate new snow density, Eq. (4) and Eq. (5), using any freshly fallen snow and old snow.
2. Apply compaction function, Eq. (6) to snowpack.
3. Calculate total snow thickness using Eq. (3).
4. Discretize the individual layer thicknesses based on total snow thickness.
5. Calculate thermal properties for each layer (Eq. (7) and Eq. (8)).
6. Use snow thicknesses and corresponding thermal properties as additional layers in the VAMPERS model.

2.2 \(i\)LOVECLIM v 1.0

2.2.1 General Description

\(i\)LOVECLIM is a “code-fork” of LOVECLIM 1.2 (Goosse et al., 2010), both which belong to a class of climate models called EMICS (Claussen et al., 2002). This type of model, as summarized by Weber (2010), “describes the dynamics of the atmosphere and/or ocean in less detail than conventional
General Circulation Models”. This simplification reduces computation time, thus making EMICs suitable for simulations on millennial timescales, incorporating the components with slow feedback effects, such as icesheets, vegetation, and permafrost. Different versions of LOVECLIM have successfully simulated past climates including the LGM (Roche et al., 2007), the Holocene (Renssen et al., 2005, 2009), and the last millennium (Goosse et al., 2005). Although there exist some different developments between iLOVECLIM and the LOVECLIM versions, both consist of the following coupled earth system components: the atmosphere (ECBilt), the ocean (CLIO), and vegetation (VECODE) (Fig. 2). ECBilt, the atmospheric model (Opsteegh et al., 1998) consists of a dynamical core with three vertical levels at 800, 500, and 200 hPa. It runs on a spectral grid with a triangular T21 truncation, which translates to a horizontal grid with a resolution of approximately 5.6 ° lat x 5.6 ° lon. The CLIO module (Goosse and Fichefet, 1999) is a 3-D ocean general circulation model with a free surface. It has 3° × 3° horizontal resolution and 20 vertical layers. VECODE, the vegetation module (Brovkin et al., 1997), is similar to VAMPER(S) in that it was particularly designed for coupling to a coarse-resolution earth system model. It is a reduced-form dynamic global vegetation model that characterizes the land surface as either trees, grass, or no vegetation (i.e. ‘bare soil’) and is computed at the same resolution as ECBilt. The plant types may be represented fractionally within each gridcell. Each model component of iLOVECLIM was originally developed separately and the reader is referred to Goosse et al., 2010 for a detailed description of components and coupling mechanisms. Furthermore, iLOVECLIM more recently was extended with other optional components including the dynamical ice-sheet model GRISLI (Roche et al., 2014) and a stable water isotopes scheme (Roche, 2013).

2.2.2 ECBilt-VAMPER(S) Coupling Description

The VAMPER(S) model will be coupled to the atmospheric component, ECBilt, within iLOVECLIM. The ECBilt-VAMPER(S) coupling will be done at each timestep (4 hours) where the land surface temperature from ECBilt is passed to VAMPER(S) and the ground heat flux from VAMPER(S) is returned to ECBilt (Fig. 3a). The land surface temperature is calculated within ECBilt as a function of the heat balance equation where the major heat fluxes across the air/surface interface are incorporated: sensible heat flux, latent heat flux, shortwave radiation, longwave radiation, and ground heat flux. The land surface temperature and ground heat flux are only communicated between components when the respective grid cell is classified as land with no overlying icesheet (i.e. Greenland/Antarctica at present day). With this coupling, the effect of changing permafrost conditions may be reflected in the climate via changes in the surface energy balance. If permafrost degrades, the subsurface acts as a thermal sink, absorbing additional energy to accommodate latent heat demands during phase change. However, at the same time, the active layer deepens, also redistributing the (seasonal) energy distribution at the surface.

When only VAMPER is employed, i.e. without the snowpack, the VAMPER ground surface temperature is assumed to be the same as the ECBilt land surface temperature. As a result no surface offset occurs. In the case of VAMPERs the snow surface temperature (i.e. at the top of the snow layer) is assumed to be the same as the ECBilt land surface temperature. This means the VAMPERs model ground temperature is buffered via the three snowpack layers as discussed in Sect. 2.1.2. This description is illustrated in Figure 3b. The ground surface temperature is the forcing that the VAMPER(S) model then uses to compute the subsurface temperature profile. This calculation, via the implicitly solved heat equation
with phase change capability, is fully described in Kitover et al. (2013). As VAMPER is a 1-D model, there is no lateral energy (heat/water) transfer between adjacent grid cells in the subsurface. Permafrost thickness is determined at an annual timestep using a computed average annual temperature profile, where any depth below or equal to 0°C is considered permafrost. Although in reality there is a freezing point depression which may occur as a result of the local pressure or dissolved salts, we are consistent with the thermal definition of permafrost from the International Permafrost Association: “ground (soil or rock and included ice or organic material) that remains at or below 0°C for at least two consecutive years”.

The land surface of ECBilt consists of a single “layer” which represents a volumetric soil water storage capacity to generate surface runoff when full. This system is referred to as a bucket model in previous text (Goosse et al., 2010). As of current, this hydrology portion of ECBilt, will not be coupled to VAMPERS. However, because the active layer is a regulator of hydrology in arctic and subarctic regions (Hinzman and Kane, 1992; Genux et al., 2009), a next step would be to expand coupling between VAMPERS and ECBilt by connecting the active layer with this bucket model.

The first phase of the coupling between VAMPERS and ECBilt will only include the land surface temperature and the ground heat flux as discussed. It should be mentioned as a caveat that additional coupling mechanisms are possible between iLOVECLIM components and VAMPER, which include hydrology and the carbon cycle, but will not be implemented for the first coupling phase.

### 2.2.3 Geothermal Heat Flux

The VAMPER(S) model requires a geothermal heat flux as the lower surface boundary. In Kitover et al. (2013), a sensitivity analysis was performed to look at the equilibrium permafrost thickness as a result of varying the geothermal heat flux and found that thickness can increase by about 70 m with every decrease in flux of 10 mW m$^{-2}$. To obtain the geothermal heat flux for every cell in the ECBilt grid, we used the recent publication of Davies (2013) who determined the median of heat flux estimates per approximately 2° x 2° latitude-longitude grid based on a combination of actual measurements, modeling, and correlation assumptions. However, due to the mismatch of grid resolutions between Davies (2013) and ECBilt, we determined for each ECBilt grid cell, a simple area-weighted average of the Davies (2013) estimates. In other words, each of the Davies grid cells was assigned a weighing factor based on the percentage of overlap with the ECBilt cells. Below is the original map from Davies (2013) and the averaged map applied in the VAMPER(S) experiments (Fig. 4). A preliminary sensitivity analysis between applying the geothermal heat flux map and applying the continental global average (approx. 60 mW m$^{-2}$) showed no noticeable difference in permafrost distribution. This result is different, however, than the noticeable sensitivity of geothermal heat flux on permafrost depth (Kitover et al., 2013).

### 2.2.4 Porosity

Another variable needed to run the VAMPER(S) model is the porosity values throughout depth, which in these experiments is down to 3000 meters deep. In previous VAMPER studies (Kitover et al., 2012;
Kitover et al., 2013), it was always assumed that the land subsurface was sedimentary rock, with a porosity of 0.3, 0.4, or 0.5. However, as shown in Kitover et al. (2013), the porosity, or water content, has a noticeable effect on equilibrium permafrost thickness. That sensitivity test showed about a 50 m difference in permafrost thickness when the porosity values (assuming a saturated subsurface) ranged between 0.3 and 0.5. Therefore, to both narrow our assumptions regarding the subsurface but still maintain the simplification necessary for the coarse horizontal grid, an additional lithological classification scheme was created as an additional VAMPER(S) model parameter. Using the recently published Global Lithological Map Database (GLiM) from Hartmann and Moosdorf (2012), their original seven categories were reclassified into ‘Bedrock (Bed)’, (e.g., granitic and metamorphic rock), and ‘Sedimentary (Sed)’ (e.g., sandstone, limestone) (Table 3, Fig. 5). In the case of ‘Bed’, the subsurface would presumably be quite consolidated/compressed, resulting in a low water content (Almén et al., 1986; Gleeson et al., 2014). ‘Bed’ was thus assigned a low porosity of 0.1, which based on sources that showed depth profiles of bedrock sites (Schild et al., 2001; Nováková et al., 2012), stayed constant with depth. On the other hand, similar to the case studies from Kitover et al. (2013), a depth porosity function from Athy (1930) was applied for the ‘Sed’ class, where the surface porosity (Φ) was assumed to be 0.40 and a decay constant (4 x 10^-4) in the exponential equation, representing the average for sandy textured soil. Similar to application of the geothermal heat flux map, a preliminary sensitivity analysis between applying the lithology map and applying a constant value (0.4) throughout the globe showed only marginal differences in permafrost distribution. This result is different, however, than the higher sensitivity of porosity on permafrost depth (Kitover et al., 2013).

3 Validation of preindustrial permafrost thickness distribution

3.1 Experimental Setup

The model experiments are performed over the whole globe where the VAMPER model is forced by ECBilt land surface temperatures. These values are the lower boundary layer of the atmosphere and are calculated using a surface heat budget (Goosse et al., 2010). Referring to Figure 3a, this means that ECBilt passes temperature values to the VAMPER(S) model (right side of Fig. 3) but no data is returned to ECBilt (left side of Fig. 3), leaving the climate unaffected from permafrost or changes in permafrost. The model experiments also include the spatially varying parameter values of geothermal heat flux and porosity provided by the new maps (described in sections 2.2.3 and 2.2.4). Two different model runs were made, one without the snow enhancement or any imposed surface offset (VAMPER) and one with the snow enhancement (VAMPERS). These two are first compared in sect. 3.2.1 of the Results & Discussion below.

Because permafrost has a very slow thermal response (Lunardini, 1995) as compared to other components in iLOVECLIM, VAMPER(S) is not forced synchronously by ECBilt. Rather, VAMPER(S) is forced continuously for 100 years and then runs offline for 900 years using the ECBilt average land surface temperature of the previous 100 years as the forcing. This asynchronous cycle is repeated for thousands of years until the VAMPER(S) model is equilibrated to the (already) equilibrated iLOVECLIM.
preindustrial climate. This scheme is illustrated in Fig. 6 (adapted from a similar figure in McGuffie and Henderson-Sellers (2005)). Equilibrium was determined when the lower boundary heat flux approximately matches the annual average ground surface heat flux. This is also when the permafrost thickness is stable. Although the model approaches a steady state through the subsurface depth, we acknowledge that in reality, some of the permafrost regions are not at equilibrium since they are responding to recent warming.

3.2 Results and Discussion

In order to verify the performance of VAMPER(S) forced by iLOVECLIM, a series of equilibrium experiments were performed for the preindustrial (PI) climate (~ 1750 AD). For comparative purposes, we assume the PI state of permafrost is similar enough to the current state of permafrost that we used modern-day data to validate against the PI simulations. The simulated areal extent was compared to present-day extent using the “Circumarctic Map of Permafrost and Ground-Ice Conditions” (Brown et al., 2014). Unlike the model validation done by Lawrence and Slater (2005), and then subsequently critiqued by Burn and Nelson (2006), our simulations attempt to capture the extent of both continuous and discontinuous permafrost. In addition, available borehole data, for sites within the arctic/subarctic, were used to evaluate the simulated thicknesses. Therefore, there are two types of validation approaches: 1) permafrost distribution and 2) permafrost depth.

3.2.1 Permafrost Distribution Validation

The first validation demonstrates the extent to which the VAMPER model reproduces the modern-day permafrost distribution. The results can be matched against a study comparing a suite of earth system models, namely the Coupled Model Intercomparison Project phase 5 (CMIP5) (Koven et al., 2013). This report gives the simulated preindustrial permafrost areas under a number of different earth system climate models and configurations. Compared to the results from our study, some of the other models’ simulated permafrost distributions cover more area while some cover less. The maximum is reported as 28.6 x 10^6 km^2 and minimum 2.7 x 10^6 km^2. Our simulation using VAMPER yields approximately 20.3 x 10^6 km^2. This is a reasonably comparable estimate since almost 80% (14/18) of the model area extents from Koven et al. (2012) fall within ±40% (12 – 28 x 10^6 km^2) of our model estimate. According to discussion by Koven et al., (2012), most of the variation seen among the compared earth system models is primarily attributed to the subsurface modeling techniques, such as water content, using a latent heat term, and differing soil thermal conductivities. Secondary causes are attributed to the air-ground coupling such as incorporation of organics and a snowpack (bulk or multilayer). These conclusions are not different from our own study in that 1) snowpack plays a marked role in permafrost modeling and inclusion/exclusion will impact the results, 2) the air-ground coupling is also a source of potential mismatch (discussed further in section 3.2.2).

Using the comparison shown in Figure 7, which overlays the simulated results on the map from Brown et al. 2014, it is clear that the experiment without the snow option overestimates permafrost extent while employing the VAMPER version underestimates it. This inaccuracy between both an overestimated result and an underestimated result is at least partially due to attempting to match results from a low
resolution grid to spatial coverage of much higher resolution. Because the marginal areas of permafrost extent are the most sensitive to climate, they are highly responsive to minor temperature deviations. These deviations, whether a few degrees above or below freezing, determine from a modeling point of view, whether permafrost exists or not. In the case of VAMPERS, average annual ground surface temperatures in many of these marginal grid cells fall below freezing while in the case of VAMPERS, the temperatures in these same grid cells now fall above freezing. However, because of the coarse grid, these estimates in either case, look like inaccurate estimates since a single value is representative of a relatively large spatial area. In reality, in these marginal permafrost regions, an area the size of an ECBilt grid cell would have only partial coverage of permafrost.

Inaccuracy in model results is also expected since we cannot parameterize some of the snowpack characteristics that alter the effect of snow on the ground thermal regime. Although we capture the role of snow cover, which is to impose a reduced thermal diffusivity effect between the air and ground, there are number of snowpack characteristics that we do not include such as rain-on-snow events and wind-induced redistribution. As opposed to our generalized snowpack parameterization scheme, described in section 2.1.1, high resolution snow models are fitted to observational data by analyzing, for example, the physics of accumulation, areal distribution, and snow-soil interactions. Therefore, it is arguable from this lack of details and the results shown in Fig. 7, whether the better option is to include a snowpack in VAMPERS or not. However, we contend that the VAMPERS model is doing a reasonable job since it is producing the surface offset that would naturally occur from the snowpack (Goodrich, 1982; Smith and Riseborough, 2002). The simulated global distribution of this surface offset is shown in Fig. 8. It is determined by calculating the difference between the mean annual ground temperature (MAGT) using VAMPERS and the MAGT using VAMPER (no snow option and no imposed surface offset). Although the maximum mean annual surface offset is about 12 °C, the average among all the grid cells that had snow cover is about 2.7 °C, which is close to our original applied surface offset of 2 °C in Kitover et al., (2013). Values between 1 °C and 6 °C were reported early on by Gold and Lachenbruch (1973). Monitoring studies of the air-ground temperature relationship also fall within this range e.g., Beltrami and Kellman (2003), Bartlett et al., (2005), Grundstein et al., (2005), Zhang (2005). However, larger values of 10 °C have been recorded in Alaska (Lawrence and Slater, 2010).

Further, without the snow option, changing precipitation patterns that can be the byproduct of a shifting climate would otherwise have no effect on the subsurface thermal conditions. In other words, the role of snow cover will be more noticeable in using the ECBilt-VAMPERS coupling when doing transient experiments. An example of the effect of changing snow conditions on the ground thermal regime come from Lawrence and Slater (2010), who demonstrated through experiments with the Community Land Model that 1) increased snowfall accounted for 10 to 30% of soil warming and 2) a shortened snow season also caused soil warming due to the ground surface’s increased uncovered exposure to air temperatures. From this point forward, all analysis is done using results from VAMPERS (i.e. with the snow option-).

In addition to the surface offset imposed by incorporation of a snowpack, there are a number of factors which have been commonly recognized in affecting the surface offset and hence should be part of the air-ground coupling. Depending on the scale of interest, the magnitude of these can vary but they
include surface organic layer, vegetation, overlying water bodies, and wind. It should be recognized that
within ECBilt, some of these factors are reflected in the land surface temperature (notably wind and a
simplified vegetation scheme) but the others are absent. In addition, coupling the ECBilt surface
hydrology to the groundwater storage would affect both the ground thermal regime and hydrological
regime. In the first case, subsurface water content affects the thermal properties of the soil. In
particular, the conductivity of organics have high variation seasonally. In the second instance, frozen
ground is impermeable, allowing little or no subsurface water storage, in turn affecting runoff flow rates
and timing.

3.2.2 Permafrost Thickness Validation

The second validation examines the simulated depth of permafrost using borehole data taken from the
Global Terrestrial Network for Permafrost (GTN-P; www.gtnp.org). The scatterplot (Fig. 9) shows all the
observed borehole measurements mapped in Fig. 10 versus the corresponding permafrost depth
simulated by iLOVECLIM. It is clear that there is a larger divergence between modeled and observed
depths for the deeper permafrost than for the more shallow observations, where the depths at some
points are overestimated by over 300 m and at some other points very underestimated by over 700 m.
There are a number of reasons to explain the mismatch, which can occur in the borehole data and/or
the model data. The first explanation is that the borehole estimates have a given range of uncertainty
since measurement techniques and subsequent interpretations are subject to error. Osterkamp and
Payne (1981) describe in detail potential errors associated with the freezing point depression, thermal
disturbance, and lithology.

The second cause is that we assumed implicitly that the observed permafrost depths are at equilibrium
with the current (or PI; preindustrial) climate state. This is probably why there is a mismatch at the
central Siberian site (66° 26’ 2” N, 112° 26’ 5” E) (point 1, Fig. 9), where the permafrost is estimated
from the borehole data to be 1000 m thick while the corresponding modeled value is only about 375 m.
It is very likely that, like much of the Siberian permafrost, this permafrost developed from the preceding
glacial period (Kondratjeva et al., 1993). Another example concerns western Siberia, (points 2 through 4,
Fig. 9), which is an area documented for having relict permafrost (Zemtsov and Shamakhov, 1992;
Ananjeva et al., 2003). It is also identified in the “Circumarctic Map of Permafrost and Ground-Ice
Conditions” (Brown et al., 2014) and “The Last Permafrost Maximum (LPM) map of the Northern
Hemisphere” (Vandenberghe et al., 2014). But it should be noted that not all the relict permafrost in
western Siberia is of late Pleistocene origin and may be from earlier cold stages (Zemtsov and
Shamakhov, 1992; French, 2007).

Another reason for some discrepancies between modeled and observed data is that high-resolution
features in the landscape and topography cannot be captured by iLOVECLIM due to the limited spatial
resolution and hence, a small set of model parameters. Such factors as vegetation and organic layer,
which can vary due to local topography and micro-climatic conditions, have been shown to affect the
active layer and ground thermal regime (Shur and Yorgenson, 2007; Fukui et al., 2008; Lewkowicz et al.,
2011; Wang et al., 2014). Consequently, given a specific borehole site, some discrepancy in the
permafrost thickness estimate will likely occur between our simplified interpretation and that which
results from including more complex and local interactions. It is possible, for example, that the observed value for point 5 (720 m) is a function of higher elevation since it is from a borehole site in the Russia Highlands but this relatively local elevation effect may not be a strong enough signal in the iLOVECLIM surface temperatures, and hence is underestimated.

The other outlying points (points 6 and 7, Fig. 9) occur in Canada but as opposed to the relict sites as mentioned above, iLOVECLIM overestimates the permafrost thickness. These discrepancies, both occurring at high latitudes of 80 °N and 76 °N, reveal that VAMPERs is not reproducing the subsurface temperatures well for this area. For example, a report for the specific borehole (Gemini E-10; point 6, Fig. 9) calculated the geothermal gradient to be approximately 0.04 °C/m (Kutasov and Eppelbaum, 2009) whereas our model result for the corresponding grid space found a gradient of approximately 0.03 °C/m. Although this difference is relatively small, it hints at either a necessary increase in the averaged geothermal heat flux used in the model or a change in the subsurface thermal properties (increase in thermal conductivity), which could be altered by an adjustment in the VAMPERs water content.

3.2.3 Climate analysis

Finally, the remaining possibility to explain inaccuracies between the modeled results and the observed results (both in reproducing spatial extent and permafrost thickness) is the iLOVECLIM climate. Results of the VAMPER(S) model, above all other parameter settings, are most dependent on the mean annual ground surface temperature, as shown in the sensitivity study from Kitover et al. (2013), so if there exists biases or discrepancies within the forcing, it will be reflected in the output. For this portion of our analysis, we took observed mean annual ground temperature (MAGT) measurements from again the GTN-P (IPY Thermal State of Permafrost Snapshot, IPA 2010). As a result, we composed a 1:1 comparison between the observed MAGT and the corresponding simulated MAGT at the same approximate depth and location (Fig. 11). Figure 12 shows a map of the selected GTN-P measurements. All the temperature comparisons are within the top thirty meters of the subsurface and therefore reflect the present or very recent climate as opposed to the deeper temperatures (i.e., > 150 m) that, depending on subsurface thermal diffusivity and surface temperature perturbations, can reflect historical temperatures of at least one hundred years ago (Huang et al., 2000) and up to tens of thousands of years (Ter Voorde et al., 2014).

Fig. 11 illustrates that VAMPERs does a reasonable job of predicting shallow subsurface temperatures since the Pearson correlation is about 0.64. This result, therefore, supports the notion that the preindustrial climate is well represented by iLOVECLIM. The points of Kazakhstan and Mongolia, and a few others in Russia, have a warm bias in the forcing (simulated is warmer than observed), which is probably due to an inaccurate representation of elevation temperature changes in iLOVECLIM, since many of those sites are at elevations above 1000 m. Even applying the lapse rate for a standard profile (6.5 C / km; McGuffie & Henderson-Sellers, 2013) would presumably make a significant difference on the depth since earlier sensitivity tests (Kitover et al., 2013) showed an average 55 m increase in equilibrium permafrost depth for every 1 °C colder. On the other hand, many of the other points show that predicted subsurface temperatures are on average a few degrees colder than the observed, leading to the most obvious conclusion that a cold bias exists in the iLOVECLIM climate. Although the cold bias,
most obvious for Canada and Alaska, is congruent to the overestimation in permafrost thickness evident from the geographic breakdown illustrated in Fig. 10, it has not previously been substantiated in former analyses of LOVECLIM or iLOVECLIM so it is more likely that such a discrepancy is due to the air-ground coupling as opposed to simply the land surface temperature forcing. Indeed, there a number of other (sub)surface processes not included in the current ECBilt-VAMPERS coupling which may reduce the apparent cold bias. These effects alter the seasonal behavior of the thermal diffusivity in the subsurface and have been well-documented in observational studies (Williams and Burn, 1996; Woo and Xia, 1996; Fukui et al., 2008). Smith and Riseborough (2002) simplified these mechanisms into the surface offset (air to ground surface) and the thermal offset (ground surface to top of the permafrost). Due to minimal complexity of the VAMPERS model, these offsets may be somewhat overlooked.

For now, the average range of error between observed and predicted is about 2.6 °C. Given that the comparisons are between point-based observations and large grid cell values, meant to represent a relatively large surface area, some variability is expected to occur.

4 Future Development

The results of this paper demonstrate the ability of VAMPERS forced by iLOVECLIM to model current permafrost distribution and thickness. The next step is to analyze the feedback that permafrost changes have on the climate. This has been of particular interest of the last decade since it is clear that specific feedbacks exist, most notably the release of locked-up carbon in the atmosphere as permafrost degrades (Anisimov, 2007). The initial method behind a full coupling would be to activate the coupling mechanisms, shown in Fig. 3, and reanalyze the equilibrium results (since a full coupling would likely lead to an altered equilibrium permafrost state). In addition, the feedback effects would be most visible during millennial-scale transient climate shifts, when major permafrost degradation and/or disappearance is likely to occur.

5 Conclusions

Enhancements have been made to the VAMPER model to make possible an estimated present-day distribution of permafrost thickness and distribution using ECBilt land surface temperatures within the iLOVECLIM equilibrated preindustrial climate as the forcing. The change in timestep to 4 hours was necessary to match the timestep of ECBilt and allow the seasonal effects, notably snow cover and the active layer, to be reflected in the simulation of permafrost. The predicted annual active layer from the stand-alone VAMPER model, under different temperature forcings, compare well with results from the Stefan equation. We also described the snow option, which introduces the thermal insulation effects and changes in the thermal properties of snow over time due to varying snow densities. In addition, we developed two new maps: geothermal heat flux and porosity. Incorporating these parameters at a global scale was an important step in improving the horizontal spatial variability of permafrost thickness/distribution while also maintaining the simplicity and efficiency of ECBilt-VAMPERS.

Equilibrium experiments for the PI climate show that when the snow component is included in the VAMPER model, the permafrost extent is noticeably reduced while the average surface offset of 2.7 °C is comparable to previous reports. We then compared both permafrost thickness estimates and
subsurface temperatures to corresponding observed values. Considering that we are comparing point
measurements to gridcell-based values, the simulations are reasonable. **There are some discussion
points around the discrepancies.** One is that the relatively coarse horizontal ECBilt grid will never
perfectly match the sensitivity of permafrost occurrence and depth due to local factors. This is also the
case in the air-land temperature coupling, where some of the local effects will simply not be present in
an EMIC. Similarly, when iLOVECLIM does not accurately represent the environmental lapse rate in areas
of higher elevation, the occurrence of permafrost in these areas are overlooked by the VAMPERS model.
Finally, some of the observed permafrost depths are not a function of the present (PI) climate, but
rather a relict presence from previous cold periods. Therefore, when comparing measured to simulated
results, some underestimations occurred. It is only with millennial-scale transient iLOVECLIM (with the
ECBilt-VAMPERS coupling) model runs that we can simulate, for example in areas of West Siberia, how
permafrost evolved over periods of major climate change.

6 Code availability

The iLOVECLIM (version 1.0) source code is based on the LOVECLIM model version 1.2 whose code is
iLOVECLIM and VAMPER(S) source code are hosted at https://forge.ipsl.jussieu.fr/ludus but are not
publicly available due copyright restrictions. Access can be granted on demand by request to D. M.
Roche (didier.roche@lsce.ipsl.fr).
