Abstract. libRadtran is a widely used software package for radiative transfer calculations. It allows to compute (polarized) radiances, irradiances, and actinic fluxes in the solar and thermal spectral regions. libRadtran has been used for various applications, including remote sensing of clouds, aerosols and trace gases in the Earth’s atmosphere, climate studies, e.g., for the calculation of radiative forcing due to different atmospheric components, for UV-forcasting, the calculation of photolysis frequencies, and for remote sensing of other planets in our solar system. The package has been described in Mayer and Kylling (2005). Since then several new features have been included, for example polarization, Raman scattering, a new molecular gas absorption parameterization, and several new cloud and aerosol scattering parameterizations. Furthermore a graphical user interface is now available which greatly simplifies the usage of the model, especially for new users. This paper gives an overview of libRadtran version 2.0.1 with focus on new features. Applications including these new features are provided as examples of use. A complete description of libRadtran and all its input options is given in the user manual included in the libRadtran software package, which is freely available at http://www.libradtran.org.

1 Introduction

Radiative transfer modeling is essential for remote sensing of planetary atmospheres, but also for many other fields in atmospheric physics: e.g., atmospheric chemistry which is largely influenced by photochemical reactions, calculation of radiative forcing in climate models, and radiatively driven dynamics in numerical weather prediction models.

The libRadtran software package is a versatile toolbox which has been used for various applications related to atmospheric radiation, a list of publications that have used the package can be found on the website http://www.libradtran.org, currently it includes more than 400 entries. Applications include the following topics (the given references are taken as examples out of the list of publications):

- Analysis of UV-radiation measurements, from which parameters like e.g. ozone concentrations, aerosol optical thickness, UV-index are derived. Since the libRadtran package originally was a radiative transfer code for the UV spectral range (the main executable is still called uvspec), the model is well established in this research area and frequently used (e.g. Seckmeyer et al., 2008; Kreuter et al., 2014).

- Cloud and aerosol remote sensing using measurements in solar and thermal spectral regions. The developed retrieval methods are for ground-based, satellite
and air-borne instruments which measure (polarized) radiances (e.g. Painemal and Zuidema, 2011; Bugliaro et al., 2011; Zinner et al., 2010; Alexandrov et al., 2012).

- **Volcanic ash studies** including remote sensing of ash mass concentrations (e.g. Gasteiger et al., 2011; Kylling et al., 2015) and visibility of ash particles from the pilot’s perspective (e.g. Weinzierl et al., 2012).

- **Remote sensing of surface properties**: a model like *libRadtran* is particularly important to develop atmospheric correction methods (e.g. Drusch et al., 2012; Schulmann et al., 2015).

- **Trace gas remote sensing.** *libRadtran* can be used as a forward model for retrievals of $O_3$, NO$_2$ and BrO from DOAS (Differential Optical Absorption Spectroscopy) measurements (e.g. Theys et al., 2007; Emde et al., 2011).

- Calculation of actinic fluxes in order to quantify photolysis rates for atmospheric chemistry (e.g. Sumińska-Ebersoldt et al., 2012).

- Determination of solar direct irradiance and global irradiance distributions in order to optimize locations of solar energy platforms (e.g. Lohmann et al., 2006) and calculation of circumsolar irradiance (Reinhardt et al., 2014).

- Simulation of satellite radiances to be used for data assimilation in numerical weather prediction models (Kostka et al., 2014).

- Validation of radiation schemes included in climate models (Forster et al., 2011), calculation of radiative forcing of clouds and contrail cirrus (Forster et al., 2012), impacts of aviation on climate (e.g. Lee et al., 2010)

- Simulation of heating rates in three-dimensional atmospheres to develop fast radiation parameterizations for Large Eddy Simulation (LES) models (Klinger and Mayer, 2014).

- Simulation of solar radiation during a total eclipse (Emde and Mayer, 2007).

- Rotational Raman scattering, which explains the filling-in of Fraunhofer lines in the solar spectrum (Kylling et al., 2011).

- Estimation of background radiation affecting lidar measurements (e.g. Ehret et al., 2008)

- Remote sensing of planetary atmospheres (e.g. Rannou et al., 2010)

Since the publication of the first *libRadtran* reference paper (Mayer and Kylling, 2005) the model has been further developed. It includes numerous new features which will be the focus of this paper.

One of the major extensions is the implementation of polarization in the radiative transfer solver MYSTIC (Emde et al., 2010), which is important because an increasing number of polarimetric observations have been performed during the last years and are planned for the future, from ground, satellite, and air-craft. These observations include more information about optical and microphysical properties of atmospheric particles than total radiances alone (Kokhanovsky et al., 2010; Mishchenko et al., 2007). Another important reason for considering polarization is that in the short-wave spectral region (below about 500 nm) the neglect of polarization can lead to large errors: more than 10% for a molecular atmosphere and up to 5% for an atmosphere with aerosol (Mishchenko et al., 1994; Kotchenova et al., 2006).

Moreover *libRadtran* now includes a solver to calculate rotational Raman scattering (Kylling et al., 2011) which affects the accuracy of trace gas retrievals. Further the Raman scattering signal can be used to estimate cloud top pressure from satellite measurements and aerosol properties from surface and satellite observations.

Numerous state-of-the-art parameterizations for aerosol and ice cloud optical properties have been included (see Secs. 5 and 6). These new parameterizations provide more accurate radiance calculations. In particular for polarized radiative transfer, which requires not only a scattering phase function but the full scattering matrix, new optical properties data were required. In order to improve the accuracy for highly peaked phase functions – which are typical for ice clouds – an improved intensity correction method has been developed and included into the DISORT solver (Buras et al., 2011), and new variance reduction methods have been developed for the Monte Carlo solver MYSTIC (Buras and Mayer, 2011). *libRadtran* has also been rewritten to allow simulations with an arbitrary number of cloud and aerosol types – which can e.g. be used to simulate variability in particle size distribution.

A new gas absorption parameterization for the solar and thermal spectral ranges has been developed (Gasteiger et al., 2014). It is available in different spectral resolutions and can be applied for the simulation of radiances and irradiances. It is particularly useful for efficient simulations of radiances measured by satellite instruments (see Sec. 4.1).

The DISORT radiative transfer solver has been translated from FORTRAN77 to the C programming language. All variables were transferred from single to double precision. These changes improved the numerical stability of the code and reduced computational time significantly (for details see Buras et al., 2011).

The paper is organized as follows: Sec. 2 provides an overview of the uvspec radiative transfer model which is the core of the *libRadtran* package. Sec. 3 gives a short de-
The model was originally designed to compute UV-radiation, therefore its name is *uvspec*. As said before it now covers the complete solar and thermal spectral range.

The usage of the model is described in the user guide which comes along with the package. The user guide includes descriptions of the RTE solvers, examples of use as well as detailed documentation of all options and respective parameters. Below *uvspec* input options are put in teletype-font, for example `rte Solver`.

The *uvspec* model may be run either from the command line using

```
uvspec < input_file > output_file
```

or from the Graphical User Interface (see Sec. 9).

## 3 Radiative transfer equation solvers

The RTE for a macroscopically isotropic medium, i.e. randomly oriented particles and molecules, may be written as

\[
\frac{dI}{ds} = -I + J
\]

(1)

where the source function \( J \) is

\[
J = \frac{\omega_0}{4\pi} \int P(\Omega, \Omega') I(\Omega') d\Omega' + (1 - \omega_0) B_e(T)
\]

(2)
Table 1. The radiative transfer equation solvers currently implemented in libRadtran.

Explanation:
- PP, plane-parallel
- PS, pseudo-spherical
- SP, fully spherical
- 1D, one-dimensional
- 3D, three-dimensional

1 is the Stokes vector (polarized radiance)

Here \( \mathbf{I} = (I, Q, U, V) \) is the Stokes vector at location \((x, y, z)\), \( \beta \) the volume extinction coefficient, \( \omega_0 \) the single scattering albedo, \( \mathbf{P}(\Omega, \Omega') \) the scattering phase matrix, and \( \mathbf{B}_c(T) = (B(T, 0, 0, 0)) \) the emission vector including the Planck function \( B(T) \). For most applications in the Earth’s atmosphere, thermal emission can be neglected for wavelengths below about 3 \( \mu \)m. Polarization is also often neglected, in this case the Stokes vector in Eqs. 1 and 2 is replaced by the radianse \( L \), the phase matrix becomes the scalar phase function \( p(\Omega, \Omega') \) and the emission vector is just the Planck function \( B(T) \).

The **uvspec** model includes various methods to solve Eq. 1. The list of solvers which may be selected using the option \( \text{rte solver} \) is shown in Table 1.

### 3.1 DISORT

The solver disort is used by default in libRadtran. DISORT (Stamnes et al., 2000) is based on discrete ordinates and allows to compute radiances, irradiances and actinic fluxes in plane-parallel geometry. The original FORTRAN77 version of the algorithm exhibited several numerical instabilities for certain combinations of geometries and optical properties. The FORTRAN77 code has been translated to C-code and is entirely in double precision (the FORTRAN77 version is mostly in single precision) and includes dynamic memory allocation (not possible in FORTRAN77). As such, the C version is numerically stable and also faster than the original FORTRAN77 version. We thus use the C version of the DISORT algorithm by default. The original FORTRAN77 version may still be invoked by fdisort2. Both the C-code and the FORTRAN77 version include the new intensity correction method for peaked phase functions by Buras et al. (2011), which is used by default.

For calculations with rotational Raman scattering, the C version has been generalized so that arbitrary source functions (not only a solar or thermal source function) can be handled (Kylling and Stamnes, 1992; Kylling et al., 2011). Rotational (inelastic) Raman scattering from other wavelengths into the wavelength, for which the radiative transfer equation is solved, is included into the source term.

### 3.2 MYSTIC

The most comprehensive solver in libRadtran is the Monte Carlo model MYSTIC (Mayer, 2009), which may be used to calculate (polarized) radiances, irradiances and actinic fluxes in the solar and thermal spectral regions. Within MYSTIC photons are traced through the atmosphere from the source towards the sensor or backwards, from the sensor to the source, which is much more efficient especially in the thermal wavelength region. One of the main applications of MYSTIC is to calculate radiances in cloudy atmospheres. The sharp forward scattering of clouds and aerosols causes numerical problems in Monte Carlo models. In order to avoid these, sophisticated variance reduction methods have been developed (Buras and Mayer, 2011). These are enabled using mc.vroom on. Solar radiation is initially unpolarized and becomes polarized by molecular, aerosol or cloud scattering in the atmosphere. With the option mc.polarisation
In order to complement the instruments that can be simulated by libRadtran, a lidar simulator called sslidar has been implemented. It only takes into account single scattering and reflection and is based on the lidar equation which is integrated over each range. Note that in order to obtain a smooth signal, the atmosphere normally has to have at least the same vertical resolution as the range width. For radar simulations a stand-alone tool is available (see Sec. 10.2).

### 3.3 Two-stream solvers

For the calculation of irradiances, two fast two-stream solvers are available.

The first solver, twostr, is described in detail in Kylling et al. (1995). twostr is optimized for calculating actinic fluxes, and hence heating rates. It can be run in plane-parallel as well as in pseudo-spherical geometry.

The second two-stream method available in libRadtran is rodents, which is based on the delta-Eddington two-stream described e.g. in Zdunkowski et al. (2007), Sec. 6.1–6.4. Based on a different two-stream approach than twostr, it naturally yields different results. In contrast to twostr, the pseudo-spherical approximation is not implemented. Also rodents is not capable of calculating actinic fluxes.

For actinic fluxes and atmospheric heating rates, twostr is the better choice. However, for calculating solar irradiances, we recommend using rodents: For cases where the resulting irradiance is not negligible (larger than 2% of the extraterrestrial irradiance), the difference between rodents and exact disort calculations is on average 5% (7%) for down(up)-welling irradiances. For twostr the values are 9% (11%). Especially in case the atmosphere is only weakly absorbing, the average differences at top-of-atmosphere (TOA) and at the surface are only 2% (1%) for rodents, whereas they are 5% at TOA and even 13% (18%) at surface for twostr.

For the thermal irradiance, rodents also gives better results at TOA (1.6%) and surface (1%) than twostr (3%). For irradiances within the atmosphere, no real preference can be given.

### 3.4 Lidar and radar simulations

In order to complement the instruments that can be simulated by libRadtran, a lidar simulator called sslidar has been implemented. It only takes into account single scattering and reflection and is based on the lidar equation which is integrated over each range. Note that in order to obtain a smooth signal, the atmosphere normally has to have at least the same vertical resolution as the range width. For radar simulations a stand-alone tool is available (see Sec. 10.2).

### 3.5 Other solvers

The solver tzs (see Appendix B) is based on the zero scattering approximation in the thermal spectral range. It may be used for clear sky calculations of irradiances at top of atmosphere (TOA). It also calculates "black cloud" radiances for the application of the CO$_2$ slicing algorithm (Smith et al., 1970; Chahine, 1974; Smith and Platt, 1978; Menzel et al., 1983; Eyre and Menzel, 1989) which may be used for the determination of cloud top temperatures from passive remote sensing measurements in the thermal spectral range.

For the solar region a fast single scattering solver sss is available. These solvers may be used for fast but approximate simulations of satellite measurements.

Several other RTE-solvers are included in uvspec for compatibility with earlier releases of the package. These include sdisort (pseudospherical disort), spsdisort (single precision, pseudospherical disort), fdisort1 (version 1 of DISORT), and polradtran (Evans and Stephens, 1991). While they may still be used, we do not recommend their use as the other solvers listed in Table 1 perform better.

### 3.6 Accuracy of solvers

MYSTIC is a physically correct model which does not include any approximations. It has been validated in many international model intercomparison studies, for radiance calculations with highly peaked phase functions (Kokhanovsky et al., 2010), for polarized radiance calculations (Emde et al., 2015), and for irradiances and irradiances 3D model domains (Cahalan et al., 2005). In all studies MYSTIC belongs to the core of models which produce equal results within their uncertainty range. MYSTIC agrees perfectly to DISORT for radiances and irradiances with only a few exceptions, e.g. for circum-solar radiation, where the second-order intensity correction included in DISORT is not accurate for highly peaked scattering phase functions (Buras et al., 2011). In Emde et al. (2011), a comparison between DISORT and MYSTIC for a radiance spectrum in the O$_2$A-band is shown. The relative difference between the solvers is here less than 0.05%. All other solvers are approximations and hence less accurate: as mentioned before the two-stream solvers are only appropriate for irradiances and the tzs solver only provides radiances in thermal atmospheres and neglects scattering completely.

The accuracy of MYSTIC depends only on the number of traced photons. The standard deviation of MYSTIC is calculated when the option mc_std is enabled. The user may...
run MYSTIC with many photons as reference for some cases in order to check the accuracy of other solvers for specific applications.

4 Molecules

4.1 Molecular absorption parameterizations

Spectral ranges affected by molecular absorption comprising a complex line structure require parameterizations to reduce the computational cost. Molecular absorption parameterizations included in libRadtran are listed in Table 2. By default the reptran parameterization is applied. Using the option mol_abs_param the user may select the most appropriate parameterization for the specific application. As an example Fig. 2 shows radiance calculations for nadir viewing direction at the top of the atmosphere using the parameterizations reptran and lowtran and line-by-line calculations. The reptran parameterization (Gasteiger et al., 2014) has recently been included in libRadtran. In reptran integrals over spectral intervals, e.g. integrated over a narrow spectral band or an instrument channel response function, are parameterized as weighted means over representative wavelengths similar to the method described by Buehler et al. (2010). The selection of an optimum set of representative wavelengths is based on accurate line-by-line simulations for top of atmosphere radiances of a highly variable set of atmospheric states. The ARTS model (Eriksson et al., 2011) including state-of-the-art continuum models and spectroscopic data from HITRAN 2004 (Rothman et al., 2005) were used to calculate the gas absorption properties. For wavelengths below 1130 nm measured absorption cross sections of O$_3$ (Molina and Molina, 1986), O$_1$ (Greenblatt et al., 1990), and NO$_2$ (Burrows et al., 1998) are included, as they are not covered by HITRAN or the continua (see also Sec. 4.2). Three band resolutions (fine: 1 cm$^{-1}$, medium: 5 cm$^{-1}$, and coarse: 15 cm$^{-1}$) are available in the solar and thermal spectral range, as well as a number of instrument channels on the ADEOS, ALOS, EarthCARE, Envisat, ERS, Landsat, MSG, PARASOL, Proba, Sentinel, Seosat, and SPOT satellites. The parameterization has been validated by comparison to high spectral resolution calculations. For solar and thermal radiation at the top of atmosphere, as well as for solar radiation at the ground, the mean parameterization error is in the range of 1%. The mean error is slightly larger than 1% for thermal radiation at the surface. The LOWTRAN band model adopted from the SBDART radiative transfer model (Ricchiazzi et al., 1998) is also included in libRadtran.

For the simulation of radiances and irradiances we recommend to use reptran because it is faster and more accurate than lowtran. Several correlated-k parameterizations with different numbers of bands, i.e. different accuracy, are included in libRadtran. For the calculation of integrated solar and thermal irradiances and heating rates the correlated-k parameterizations by Kato et al. (1999) and Fu and Liou (1992, 1993) are recommended. Also for the calculation of heating/cooling rates in the higher atmosphere (above 20 km) we recommend these parameterizations because reptran and lowtran are affected by large errors.

4.2 Molecular absorption cross sections

For the spectral region from 160 to 850 nm libRadtran includes measured absorption cross sections of various molecules in the atmosphere (see Table 3). Using the option mol_abs_param crs these cross sections are used instead of the default reptran parameterization. For wavelengths below 500 nm reptran yields approximately the same results as mol_abs_param crs because the cross sections from HITRAN and the continua are very small at these wavelengths and the same measured cross sections are relevant in both cases. For O$_2$ for instance the cross section data include the Schumann-Runge bands between 176 and 192.6 nm and the Herzberg continuum between 205 and 240 nm. Ozone absorption bands are for example the Huggins bands between 320 and 360 nm and the Chappuis bands between 375 and 650 nm. Using the option crs_model the user may specify which cross section data should be used in the simulations. Alternatively with crs_file the users may specify their own absorption cross section data.

4.3 Line-by-line calculations

In the shortwave infrared, thermal infrared and microwave region we find a huge number of absorption lines which are due to vibrational or rotational transitions in molecules. A line-by-line model is required in order to calculate spectrally resolved radiances. Line-by-line models take the absorption line positions as well as line strength parameters from spectral databases like HITRAN, calculate line broadening which depends on pressure and temperature in the atmosphere and finally obtain absorption optical thickness profiles. libRadtran does not include a line-by-line model but it allows to specify absorption optical thickness profiles using the option mol_tauf_file abs. It is convenient to use the ARTS model (Eriksson et al., 2011) to generate spectrally resolved molecular absorption data because it outputs the format required by libRadtran. ARTS includes a comprehensive line-by-line module, it allows to use different spectroscopic databases like HITRAN as input and it also includes various state-of-the-art absorption continuum models. The toolbox Py4CATS (Schreier and Böttger, 2003; Schreier, 2006; Schreier and Kohlert, 2008) which can be downloaded from www.libradtran.org also includes convenient command line programs to generate spectrally resolved absorption data. The Py4CATS tools however do not include continuum mod-
Fig. 2. Nadir top of the atmosphere radiance in the oxygen-A band around 760 nm (left) and in the IR window region (right) for the midlatitude-summer atmosphere of Anderson et al. (1986). All calculations were performed with the MYSTIC solver using the “absorption lines importance sampling” method (Emde et al., 2011). (Top) High spectral resolution calculation, based on line-by-line absorption cross sections calculated using ARTS (Eriksson et al., 2011); (bottom) pseudo-spectral calculations using the representative wavelengths band parameterizations (reptran) with different resolutions and lowtran. For comparison see also Fig. 3 in Mayer and Kylling (2005) which shows transmittances for genln2 line-by-line calculations and lowtran for the same spectral regions.

Rayleigh scattering cross sections

The Rayleigh scattering cross sections are by default calculated using Eqs. 22–23 of Bodhaine et al. (1999). The Rayleigh phase matrix for $\delta=0$ is shown in Fig 3. For calculations neglecting polarization only the $(1,1)$ element of the phase matrix which corresponds to the scattering phase function is required.

### 5 Aerosols

Besides the models by Shettle (1989) which are described in Mayer and Kylling (2005), libRadtran now includes additional aerosol properties based on the OPAC database (Hess et al., 1998). OPAC provides the required parameters for single scattering calculations: size distribution parameters, refractive indices, and the density of the material. Data are available for the spectral range from 250 nm to 40 $\mu$m for the following basic aerosol types: insoluble (inso), water soluble (waso), soot (soot), sea salt accumulated (ssam), sea salt coarse mode (sscm), mineral nucleation mode (minm), mineral accumulated mode (miam), mineral coarse mode (micm), mineral transported (mitr) and soluble sulfate aerosol (suso). For the soluble aerosols the parameters depend on humidity because the aerosol particles swell in humid air. Relative humidities of 0%, 50%, 70%, 80%, 90%, 95%, 98% and 99% are included in OPAC. The option aerosol_species_file allows to define arbitrary mixtures of these basic types or to select predefined mixtures from OPAC like e.g. continental_average, for which uvspec automatically uses the optical properties closest to the background humidity profile.

Optical properties of all basic aerosol types were calculated using libRadtran’s Mie tool (see Sec. 10.1). For mineral aerosols, which are highly aspherical, we additionally provide optical properties calculated with the T-matrix method (Mishchenko and Travis, 1998) assuming an aspect ratio distribution of prolate spheroids as described by Koepke et al. (2015).

As an example Fig. 3 shows the phase matrix elements of the basic OPAC aerosol types, of liquid cloud droplets with an effective radius of 10 $\mu$m and the Rayleigh scattering phase matrix. Note that for spherical particles only 4 elements of the 4x4 scattering phase matrix are independent whereas for aspherical particles 6 elements are required (see e.g. Hansen and Travis, 1974). Fig. 4 shows the absorption and the scattering optical thicknesses (integrated from the surface to the top of the atmosphere) for the standard aerosol mixtures in the spectral region from 300 to 800 nm. As expected, the optical thickness of the urban aerosol is the largest and that of the antarctic aerosol the smallest. In general the continental aerosol mixtures show a stronger wavelength dependency than the maritime mixtures.

The users may also provide their own optical properties data which may be generated using libRadtran’s Mie tool or other external programs; more detailed instructions are provided in the libRadtran user guide.
Fig. 3. Phase matrix elements for the basic OPAC aerosol types “water soluble” (waso), “sea salt accumulated mode” (ssam), and soot, for a water cloud with a droplet effective radius of 10 µm, and for Rayleigh scattering (with δ=0) at a wavelength of 350 nm. θ is the scattering angle, i.e. the angle between incoming and scattered directions.

Fig. 4. Absorption (left) and scattering (right) optical thickness for various aerosol mixtures specified using the option aerosol_species_file. The aerosol optical properties as well as the mixtures have been generated based on OPAC (Hess et al., 1998) parameters.

6 Clouds

6.1 Water clouds

Table 4 summarizes the parameterizations of water cloud optical properties which may be selected in libRadtran using the option wc_properties.

For the simulation of irradiances and heating rates it is normally sufficient to use a simple parameterization to convert from cloud liquid water content and droplet effective radius to the respective optical properties: extinction coefficient, single scattering albedo, and asymmetry parameter. For this purpose libRadtran includes the parameterization generated by Hu and Stamnes (1993).

For the simulation of radiances more accurate optical properties are needed and the phase function should not be approximated by a Henyey-Greenstein function as it is done in Hu and Stamnes (1993). Therefore, we have pre-calculated cloud optical properties using libRadtran’s Mie tool assuming that the cloud droplets are gamma distributed:

\[
n(r) = N r^\alpha \exp \left( -\frac{r}{r_{\text{eff}}} \right) \quad \alpha = \frac{1}{v_{\text{eff}}} - 3
\]  

Calculations have been performed for effective radii \( r_{\text{eff}} \) from 1 µm to 25 µm with a step width of 1 µm. The effective variance was set to a value of \( v_{\text{eff}} = 0.1 \) and the constant \( N \) was determined by normalization. The size distributions were cut off at a minimum radius of 0.02 \( r_{\text{eff}} \) and a maximum radius of 8 \( r_{\text{eff}} \). The size distribution bins are sampled on a size parameter \( \left( \frac{2 \pi r^2}{\lambda} \right) \) grid with a resolution of 0.003. This fine resolution is necessary to obtain smooth phase matrices. The pre-calculated data includes the wavelength ranges from 250 nm to 2200 nm (solar) with a resolution of 10 nm and the range from 2.2 µm to 100 µm (thermal) in 100 steps of equal wavenumbers. The refractive index of water has been taken from Warren (1984). In the solar (thermal) region the phase matrices are computed from 5000 (500) Legendre polynomials. In the optical properties files 129 of the Legendre polynomials are stored, as well as the phase matrix elements, which are stored on scattering angle grids \( \theta \) optimized such that the error of the phase matrix – when interpolated linearly in \( \cos \theta \) between the grid points – is smaller than 1%. As an example Fig. 3 shows the four phase matrix elements of a cloud droplet distribution with \( r_{\text{eff}} = 10 \) µm at 350 nm. Here the cloudbow at \( \theta \approx 140^\circ \) is clearly visible in the \( P_{11} \) and \( P_{12}/P_{11} \) elements of the phase matrix. \( P_{12}/P_{11} \) corresponds to the degree of polarization in the principal plane after single scattering, it can be seen that the maximum in the cloudbow region is about 80%. The mystic solver uses the phase matrix stored on the \( \theta \)-grid, whereas all other solvers use the Legendre polynomials, except for the intensity correction in disort which uses the phase function (see also Buras et al., 2011).

For specific applications, e.g. different size distributions, the user can easily generate optical properties using libRadtran’s Mie tool.

6.2 Ice Clouds

For ice clouds libRadtran includes a variety of parameterizations (see Table 5) from which the user may select the most appropriate one for a specific application by specifying the option ic_properties. Ice clouds are more complex than water clouds because they consist of ice crystals of different shapes. Some of the ice cloud parameterizations allow the ice crystal habit (ic_habit) to be specified.

As described in the previous section the exact phase matrix is not needed when irradiances are calculated. For this purpose the parameterizations by Fu (1996); Fu et al. (1998) and Key et al. (2002) are included in libRadtran. Fu (1996) and Fu et al. (1998) approximate the phase function by a Henyey-Greenstein function. Key et al. (2002) is slightly more accurate because it uses a double-Henyey-Greenstein function which represents the backscattering of ice crystals much better. The parameterization is based on single scattering calculations for various ice crystal habits and on measured size distributions. It is available in the wavelength range from 0.2 to 5 µm. Based on single scattering data provided by P. Yang and on the size distributions from J. R. Key we have extended the original parameterization by Key et al. (2002) to the thermal wavelength region up to 100 µm.

For accurate radiance calculations the parameterizations by Baum et al. (2005a,b) (baum) and the newer one by Heymsfield et al. (2013); Yang et al. (2013) and Baum et al. (2014) (baum_v36) are available: bau is includes full phase functions for a mixture of particle shapes, the parameterization is based on single scattering properties of smooth ice crystals and on a large number of measured size distributions. bau_v36 includes full phase matrices and three different habit models: a general habit mixture similar to bau but for rough ice crystals, and the single habits solid-column and aggregate, both of them severely roughened.

We have generated two further parameterizations (hey and yang2013) for individual habits which also include the full phase matrices (see Appendix A): hey is available for the wavelength region from 0.2 to 5 µm for smooth particles in the effective radius range from 5 to 90 µm. The full wavelength region from 200 nm to 99 µm is available for yang2013, effective radii may be in the range from 5 to 90 µm and a roughness parameter may also be specified, ranging from smooth to severely rough. For the yang2013 parameterization, the single scattering properties of nine individual ice crystal habits which are commonly observed in ice clouds have been taken from the database by Yang et al. (2013). The hey parameterization was generated before this database existed and it is based on single scattering data provided by Hong Gang who used the improved geometrical optics method (IGOM), the same method as used by Yang et al. (2013).

Please refer to the libRadtran user guide for a list of available habits for each parameterization.

Fig. 5 shows the phase matrix elements of ice crystal distributions with an effective radius of 40 µm at 550 nm wavelength. The red lines correspond to smooth crystals and the blue lines to severely rough crystals. The individual habits are for the yang2013 parameterization. General habit mixtures which are available for the hey parameterization based on smooth crystals and for the bau_v36 parameterization based on severely rough crystals are also shown. For most smooth crystals and also for the general habit mixture ghm of the hey parameterization scattering features of hexagonal ice crystals, the most prominent being the halo at 22° scattering angle, are visible in all phase matrix elements. The phase matrices for severely rough crystals do not show halo features and they are relatively similar for all habits. In reality ice clouds are highly variable: There are situations when the halo is visible, in this case obviously there must be regular smooth ice crystals in the cirrus clouds. When no halo is visible, the assumption of severely roughened crystals might be more realistic.

Explanation: D: DISORT M: MYSTIC
RTLSR: RossThickLiSparseReciprocal model, optionally with hot spot parameterization

### 7 Surface

#### 7.1 Bidirectional reflectance distribution functions

All solvers included in *libRadtran* may include Lambertian surfaces, while disort and MYSTIC can also handle bidirec-

---

*libRadtran* provides a variety of BRDFs, which are listed in table 6.
mainly on wind speed and to a lesser degree on plankton concentration and salinity. For the MYSTIC solver, also the wind direction can be set. In contrast to vegetation where the typical hot spot occurs in the 180° backscatter direction, the main feature for water is specular reflection. The parameterization in uvspec was adopted from the 6S code (Vermote et al., 1997) and is based on the measurements of Cox and Munk (1954a,b) and the calculations of Nakajima and Tanaka (1983). A vector version of the ocean parameterization, developed by Tsang et al. (1985) and Mishchenko and Travis (1997), is available for polarization calculations with MYSTIC. The vector version uses only wind speed as a parameter and does not take into account plankton concentration, salinity or wind direction.

Finally, the parameterization of the surfaces of extraterrestrial solid bodies such as the moon, asteroids or the inner planets by Hapke (1993) is available.

Only the ocean BRDF parameterizations depend directly on the wavelength. For all other BRDF models, the parameterization can either be given as being constant with wavelength (by using e.g. the option brdf_rpv), or as a file containing the parameters for each wavelength (using e.g. brdf_rpv_file).

### 7.2 Fluorescence

For vegetation covered surfaces, a weak solar-induced chlorophyll fluorescence signal is emitted in the red and far-red spectral regions. The contribution of fluorescence to the radiance leaving the bottom boundary is

\[ L_F^F(\mu, \phi, \lambda) = F(\lambda), \]

where \( F(\lambda) \) is the fluorescence source in the same units as the incoming solar flux at the top of the atmosphere (for example mW/(m² sr)). The fluorescence source of radiation is included in the disort solver. It may either be constant or vary as a function of wavelength. Additional surface bidirectional reflection of radiation may also be included. The fluorescence source depends on the solar radiation impinging the vegetation and the type of vegetation. Output from vegetation fluorescence canopy models such as that described by Miller et al. (2005), may readily be used by uvspec.

### 8 Implementation improvements

#### 8.1 Multiple atmospheric constituents

The previous versions of libRadtran were restricted to using at most four types of atmospheric constituents: molecules, aerosols, and water and ice clouds. Any user defined constituent could only be included by replacing e.g. water clouds with them. Also, it was not possible to use several types of ice cloud habits at the same time.

A recent major internal restructuring of the libRadtran code has now made it possible to use any number of...
atmospheric constituents for a radiative transfer simulation. The number is only limited by computational memory and time. The new input options needed for loading the additional constituents are profile_file and profile_properties. They work very similar to the cloud input options; merely the name of the constituent needs to be defined.

This option increases the flexibility of libRadtran in many ways. E.g. it can be used to load the optical properties for each size bin of an aerosol or water or ice cloud. This way, the size distribution may differ between the atmospheric layers. An example can be found in Kylling et al. (2013).

8.2 Change of nomenclature and backward compatibility

As the number of input options had grown to more than 300 over the years, we decided to restructure the language of the input options. The input options now have a largely consistent naming and their usage follows certain rules, making it more easy to find related input options.

We have included a python script in order to provide backward compatibility for long-established libRadtran users. The script can be found in the directory src_py. By invoking the command

```
python translate.py input_file > new_input_file
```

input files written in the old nomenclature will be translated to the new nomenclature automatically. Alternatively, the old input file can be sent directly to uvspec with the following command:

```
python translate.py input_file | uvspec
```

9 Graphical User Interface

The large number of input options available in the uvspec model may appear overwhelming. To help the user to create uvspec input files a graphical user interface (GUI) has been developed. The GUI organizes the input options in logical groups such as “Molecular Atmosphere”, “Aerosol”, “Surface” etc., see also the grey bar at the top in Fig. 6. Input options that are set by the user and will be written to the new input variable.

Input options that refer to input data files, such as wavelength dependent surface albedo, may be plotted from the GUI. In the example in Fig. 6, the extraterrestrial surface flux (upper left subplot), the surface fluorescence spectrum (lower left subplot) and surface albedo (lower right subplot) inputs are plotted. Note that the wavelength coverage (x-axis) differs reflecting the different wavelength regions included in the input data files.

Once all wanted input options are set, they are saved to a user specified file, and uvspec is run from within the GUI. The output from the run may readily be plotted using the GUI. For example, in Fig. 6, the calculated nadir radiance at the top of the atmosphere is shown in the upper right subplot. The GUI includes numerous working examples. Users may add more examples to the GUI specific to their interests.

10 Other tools

Several additional tools are included in the libRadtran package. An overview is given in Mayer and Kylling (2005, Tab. 4). New tools are ssradar, a single scattering Radar simulator (see below), and pmom, which calculates Legendre polynomials for a given phase function.

10.1 Mie calculations

The tool for Mie calculations (mie) has been extended considerably. The user may select between two Mie codes, MIEV0 by Wiscombe (1980) or mhmie by Bohren and Huffman (1983). The tool allows to generate input optical properties for uvspec calculations for arbitrary size distributions. It generates full phase matrices which are stored on optimized angular grids for a user-defined accuracy. The radiative transfer solvers MYSTIC and DISORT with the new intensity correction method (Buras et al., 2011) use the phase functions/matrices rather than Legendre polynomials, which are calculated by the Mie codes.

10.2 Single scattering Radar simulator

Single scattering Radar (ssradar) is a stand-alone 1D pure Rayleigh-scattering cloud radar simulator that handles arbitrary cloud layers and droplet size distributions as well as tilted viewing angles and supercooled water droplets. The radar reflectivity factor is calculated directly from the droplet distribution with

\[ Z = \sum_i n_i D_i^6 \] (Rinehart, 2010) where \( D \) is the droplet diameter and \( n_i \) the distribution number density for the discrete interval \( D_i, D_{i+1} \). Internally available distributions are gamma and lognormal, arbitrary distributions can be entered using input files.
11 Some applications

The *libRadtran* package has been used for numerous applications. Many of these are listed under the publications link at http://www.libradtran.org. The examples directory also includes a number input files that may be used especially by new users to create input files. Below some applications of *libRadtran* are described.

11.1 *uvspec* and ARTS

The high number of absorption lines in the shortwave infrared and the thermal infrared requires a line-by-line approach to resolve the spectral structure. Below is shown how molecular absorption data from ARTS may be combined with *uvspec* to perform line-by-line calculations in both the solar and thermal parts of the spectrum. For both examples the spectral resolution, the molecules to be included and the line function properties are specified in the input to ARTS. It is noted that the same ambient atmospheric profile should be used in both, ARTS and *uvspec*.

11.1.1 Solar source

Solar induced chlorophyll fluorescence is emitted in the 660 to 800 nm spectral region with two broad peaks at about 685 and 740 nm. In this spectral region are the O$_2$-A and O$_2$-B bands which contain a large number of absorption lines. Although the fluorescence signal is weak, especially the O$_2$-B region holds promise for retrieval of vegetation fluorescence from spectrally high resolution space borne instruments (Guanter et al., 2010). In this spectral region the surface albedo is typically low while there is a fluorescence peak around 685 nm (see red line lower plot Fig. 7). The optical depths from ARTS are input to *uvspec* which calculates the top of the atmosphere radiance (blue line, upper plot of Fig. 7) including the fluorescence signal (red line, lower plot of Fig. 7), surface albedo (green line, lower plot of Fig. 7) and molecular scattering. Measurements may be made at a lower spectral resolution. The lower plot of Fig. 7 shows radiance spectra convolved with a triangular spectral response function with a full width at half maximum (FWHM) of 0.3 nm using the *conv* tool of *libRadtran*. The spectral response function was generated with the *make_slitfunction* tool. Spectra with (blue line) and without (purple line) fluorescence are presented. It is seen that the fluorescence signal is relatively
The Infrared Atmospheric Sounding Interferometer (IASI) on board the MetOp satellite measures the radiance from 645 to 2760 cm\(^{-1}\) (15.50-3.6 \(\mu\)m) with a spectral resolution of 0.25cm\(^{-1}\). Its main purpose is high-resolution atmospheric sounding of temperature and humidity, and trace gas column retrievals (Clerbaux et al., 2009; Hilton et al., 2011). It may also be used to detect volcanic ash (see Clarisse et al., 2013, and references therein).

The left panel of Fig. 8 shows IASI spectra from a granule covering the ash cloud following the eruption of Mt. Kelud, Indonesia, in February, 2014. The spectra are classified as cloudless (green), ice cloud (blue), and volcanic ash (red). To investigate the realism of this identification the spectra were simulated with ARTS/uvspec. For all simulated spectra, the surface emissivity was set equal to one which is representative for water. The simulated spectra are shown in the right plot of Fig. 8.

The cloudless spectrum has brightness temperatures representative for the ocean at these latitudes. The main molecular absorption features in this part of the spectrum are water vapor lines throughout the spectrum, ozone (broad band feature centered around 1050 cm\(^{-1}\)), and CO\(_2\) (feature below 800 cm\(^{-1}\)). The data from ARTS include absorption lines from these molecules. In the cloudless spectrum the ozone band around 1050 cm\(^{-1}\) is colder than the radiation at lower and higher wavenumber, indicating that the radiation in the ozone band was emitted at a higher and colder altitude than the surface. Overall the ARTS/uvspec cloudless spectrum agrees well with the measured spectrum.

For the simulation with an ice cloud, the ice cloud was located between 12 and 13 km. Ice water content was set to 1 g/m\(^3\). The ice particles were assumed to consist of solid columns with \(r_{\text{eff}}=40.0 \mu\)m. The ice cloud parameterization \texttt{ic.properties yang} was selected. The spectrum identified as ice cloud (blue curve in left plot of Fig. 8) appears saturated for nearly all wavenumbers except for the ozone band centered around 1050 cm\(^{-1}\). The rather low brightness temperature and wavenumber independent behaviour outside the ozone band, indicates that this is an ice cloud and that it is opaque. The simulation with an ice cloud (blue curve in right plot of Fig. 8) agrees well with the measured spectrum. The higher temperatures in the ozone band implies that this radiation was emitted at a higher altitude in the stratosphere where the temperature is higher than at the altitude of the cloud.

The ash simulation included an ash cloud between 17 and 18 km. The ash particles were assumed to be made of andesite, spherical and mono-disperse with a radius of 3 \(\mu\)m. The refractive index of andesite was taken from Pollack et al. (1973) and the optical properties were calculated using the \texttt{mie} tool. The ash density was \(1 \times 10^{-3} \text{ g/m}^3\) which corresponds to a mass loading of 1 g/m\(^2\) for a 1 km thick cloud.

The red curve in the left plot of Fig. 8 is classified as ash using the difference in brightness temperature method described by Clarisse et al. (2010). This spectrum is colder than the cloudless spectrum indicating a colder effective emitting temperature overall. The general spectral shape is similar to the cloudless spectrum below 1000 cm\(^{-1}\). Above about 1200 cm\(^{-1}\) the brightness temperature of the cloudless spectrum generally decreases with increasing wavenumber, while the converse is true for the ash spectrum. The simulated ash cloud spectrum (black curve in right plot of Fig. 8) differs from the measured spectrum classified as ash. Both the simulated and measured ash spectra increase in magnitude with increasing wavelength above 1100 cm\(^{-1}\), but the simulated spectrum increases more. Below about 900 cm\(^{-1}\) the spectral behavior of the measured and simulated spectra differs. This may be due to either wrong assumptions about the ash type and hence refractive index and/or the mixing of ice with ash. Ice clouds have an opposite effect of ash clouds on the bright-
ness temperature between 800-1000 cm$^{-1}$, whereas above 1075 cm$^{-1}$ ice clouds have only a very weak dependence on wavenumber (see Fig. 2 of Gangale et al., 2010). To test if the presence of both ash and ice could reproduce the measured spectrum, simulations were made with both an ash cloud and an ice cloud. The altitude and thickness of the clouds were as above, but the ash cloud density was $2 \times 10^{-4}$ g/m$^3$ and the ice water content $1.5 \times 10^{-2}$ g/m$^3$. The resulting spectrum is shown in maroon in the right plot of Fig. 8. The mixed scene with both ash and ice is seen to well reproduce the measured ash spectrum in the left plot of Fig. 8.

11.2 Simulated satellite image

Fig. 9 shows a simulated satellite image (top) and the corresponding observation (bottom). Three visible channels of the SEVIRI instrument on the MSG (Meteosat Second Generation) satellite were simulated based on input data from the operational COSMO-DE forecast (Baldauf et al., 2011) of Deutscher Wetterdienst for the 15th July 2012, 12 UTC. The spatial resolution of the simulation is 2.8 km$\times$2.8 km, that of the SEVIRI observation is 3 km$\times$3 km at the sub-satellite point. A false color composite was generated using the simulated radiance of the 1.6 $\mu$m channel for red, the 0.8 $\mu$m radiance for green and 0.6 $\mu$m radiance for blue. The simulations were performed using the one-dimensional disort solver. The MODIS surface albedo dataset was used (Schaaf et al., 2002) to set the Lambertian surface albedo. The effective radii of liquid clouds were parameterized according to Martin et al. (1994), and for the optical properties the mie parameterization was applied. Ice cloud effective radii were

Fig. 9. Top: Simulation of MSG-SEVIRI image. False color composite, where red corresponds to the 1.6 $\mu$m channel, green to 0.8 $\mu$m and blue to 0.6 $\mu$m. The simulation was performed using the disort solver with input data from the operational COSMO-DE forecast for the 15th July 2012, 12 UTC. The axes correspond to SEVIRI pixel. Bottom: Corresponding SEVIRI image.
parameterized according to Wyser (1998) and for the corresponding optical properties the parameterization `baum_v36` was used with the general habit mixture. Molecular absorption was included using the `reptran` parameterization. In the false color composite water clouds appear white and ice clouds appear blueish, because ice absorbs in the region about 1.6 \( \mu \text{m} \). The simulated image looks very similar to the observation. A major difference is that the ice clouds in the observation appear more blueish, the reason is that their real optical thickness is larger than in the COSMO-DE forecast.

### 11.3 Polarization

The MYSTIC solver can be applied to simulate multi-angle multi-spectral polarized radiances using the option `mc_polarisation` (Emde et al., 2010). Polarized radiative transfer using MYSTIC has been validated in extensive model intercomparison projects (Kokhanovsky et al., 2010; Emde et al., 2015).

Fig. 10 shows an example for simulations at wavelengths of 443, 670 and 865 nm; these are measured by the POLDER (Polarization and Directionality of the Earth’s Reflectances) instrument onboard PARASOL (Polarization and Anisotropy of Reflectances for Atmospheric Sciences coupled with Observations from a Lidar) (Deschamps et al., 1994). All simulations are for a solar zenith angle of 30° and show the reflected radiances (normalized to incoming solar irradiance) at the top of the atmosphere in the solar principal plane. The viewing angle of 30° corresponds to the exact backscattering direction. The angular resolution is 2°. All simulations are for the US standard atmosphere. The figure shows the first and second components of the Stokes vector \( I \) and \( Q \); the components \( U \) and \( V \) are exactly 0 in the principal plane for symmetry reasons.

The first row shows the results for a clear atmosphere, i.e. Rayleigh scattering and molecular absorption. Here \( I \) is largest for the shortest wavelength because the Rayleigh scattering cross section decreases with \( \lambda^{-4} \), where \( \lambda \) is the wavelength. The absolute value of \( Q \) also increases with increasing Rayleigh scattering cross section. A negative \( Q \) means that Rayleigh scattering polarizes perpendicular to the scattering plane, which, for single scattering, corresponds to the principal plane for this geometry.

The second row of the figure shows the same simulation but with an underlying ocean surface, which is modelled according to Mishchenko and Travis (1997) (`bpdf_tsang`). The wind speed was set to 2 m/s. \( I \) and \( Q \) clearly show the sun glint which has a maximum at a viewing angle of about -30° and which is highly polarized. The intensity of the sun glint increases with increasing wavelength since the incoming radiance at the surface becomes less diffuse when there is less Rayleigh scattering in the atmosphere.

The third row shows the result for desert aerosol as defined in the OPAC database (`aerosol_species_file desert`), with an underlying Lambertian surface albedo of

![Fig. 10. Stokes vector components I and Q at wavelengths of 443 nm (blue solid lines), 670 nm (green dashed lines), and 865 nm (red dashed-dotted lines) for various atmospheric setups (see text for details). The radiances are calculated at the top of the atmosphere for viewing angles from -50° to 50°, where 0° corresponds to the nadir direction.](image-url)
0.3. \( I \) shows a backscatter peak at 670 and 865 nm. \( Q \) looks similar as for Rayleigh scattering, however there are differences mainly around the backscatter region. At wavelengths of 670 and 865 nm, \( Q \) has a minimum in the exact backscatter direction and becomes positive for viewing angles around 90° this direction.

The fourth row shows a simulation including a water cloud (\texttt{wc.properties mie}) in 2-3 km altitude with an optical thickness of 10 and an effective droplet radius of 10 μm. \( I \) and \( Q \) show the glory about the backscatter direction and the rainbow at a viewing angle of about -10° corresponding to a scattering angle of 140°. In \( Q \) the rainbow is more pronounced than in \( I \) because \( Q \) is less affected by multiple scattering. The angular resolution shown here is not sufficient to separate the glory from the backscattering peak in \( I \). The sign of \( Q \) in the rainbow region is the same as for Rayleigh scattering whereas it is opposite in the glory region, which means that the rainbow is polarized perpendicular to the scattering plane whereas the glory is polarized parallel to the scattering plane.

The last two rows show simulations with ice clouds, where we have used the \texttt{yang2013} parameterization. An ice cloud layer with an optical thickness of 2 was included at an altitude from 9–10 km. The selected habit was \texttt{solid column} and we performed simulations for smooth crystals and for severely rough crystals respectively. The effective crystal radius in both simulations is 30 μm. The smooth crystals show a backscatter peak in \( I \) and a positive \( Q \) about the backscatter direction. Also there are some smaller features in \( I \) and \( Q \). The radiances (\( I \) and \( Q \)) for rough crystals are smooth functions of viewing angle. This different behaviour has been used to determine the fraction of smooth crystals in ice clouds from POLDER measurements (Cole et al., 2014).

### 11.4 Fully spherical geometry

MYSTIC can be operated in fully spherical geometry (\texttt{mc_spherical 1D}). The implementation of 1D spherical geometry is described in Emde and Mayer (2007) where it has been used to simulate radiation in the umbral shadow of a solar eclipse. A comparison to measurements during the total eclipse in Greece in March 2006 (Kazantzidis et al., 2007) showed a very good agreement for modeled and measured UV irradiances, which decreased during totality by 2 to 3 orders of magnitude depending on wavelength.

Fully spherical geometry has also been used to simulate actinic fluxes at high solar zenith angles up to 92° (Sumiańska-Ebersoldt et al., 2012).

Another interesting application is the simulation of polarized radiance at the surface at twilight, because polarized radiance measurements at twilight can be used to retrieve aerosol optical properties (e.g. Saito and Iwabuchi (2015)).

As an example we calculated polarized clear sky radiances for solar depression angles up to 9° for the US-standard atmosphere and default Rayleigh scattering and absorption settings. Fig. 11 shows the result as a function of viewing zenith angle. The relative azimuth angle between sun and observer is 0° which means that the observer looks into the direction of the sun. We see that the intensity decreases by about four orders of magnitude for solar depression angles between 0° (sun at horizon) and 9° (sun 9° below horizon). The degree of polarization (not shown) at a viewing angle of 5° is more than 90%. All results agree to published results by Blättner et al. (1974), which indicates that fully spherical geometry works correctly in MYSTIC.

**Fig. 11.** Twilight radiance at 500 nm and 700 nm calculated using fully spherical geometry for the US-standard atmosphere. The lines are for different solar depression angles. The x-axis corresponds to the viewing zenith angle.

### 12 Summary

We have presented the \texttt{libRadtran} software package (version 2.0.1), which is a comprehensive and powerful collection of tools for radiative transfer simulations in the Earth’s atmosphere. It is user-friendly, well-documented and is widely used in the scientific community. We have described various new features and parameterizations which have been included after the first publication of \texttt{libRadtran} in 2005. New features are for example a vector radiative transfer solver and a solver for rotational Raman scattering. The package includes state-of-the-art parameterizations for aerosol and ice cloud optical properties and a newly developed efficient absorption parameterization.

### 13 Code availability

The \texttt{libRadtran} package was initiated about 20 years ago and is still under continuous development. Regularly up-
dated versions of the package are available from http://www.libradtran.org.

The website includes all released versions of the package. The latest release is version 2.0.1 and includes the source code, example input files, several tests, and the graphical user interface. Additional data packages containing optical properties of clouds and aerosols and the REPTRAN gas absorption parameterization are also available. Alternatively version 2.0.1 and the additional data are available as supplement to this model description paper. The 1D version of MYSTIC is part of the libRadtran public release. Please note that the 3D version of MYSTIC is not part of the libRadtran public release, it is available in joint projects.

Appendix A

Ice crystal optical properties parameterizations

The parameterization yang2013 is based on the single scattering data by Yang et al. (2013). It is available for nine habits and three roughness parameters. It includes full phase matrices for the spectral range from 200 nm to 99 μm. The hey (Hong Emde, Yang) parameterization is available for six individual smooth habits and includes the full phase matrices for the wavelength region from 0.2 to 5 μm. The single scattering properties for the six ice crystal habits have been generated by Hong Gang based on the improved geometrical optics method (IGOM), the same which is applied in Yang et al. (2013).

In order to obtain bulk scattering properties (required by the RTE solver) the single scattering properties need to be integrated over the particle size distribution. In reality the size distributions are highly variable, for radiative transfer simulations they are often approximated by simple gamma distributions (e.g. Evans, 1998; Heymsfield et al., 2002; Baum et al., 2005a,b) or bi-modal gamma distributions (Mitchell et al., 1996; Ivanova et al., 2001). We assume a gamma size
distribution to compute the bulk scattering properties as for the water cloud properties (compare Eq. 4):

\[ n(r_e) = N r_e^{3} \exp \left( -\frac{r_e}{ab} \right) \]  

(A1)

Here \( r_e \) is a measure of the particle size (the radius in case of spherical particles) and \( N \) is the normalization constant so that the integral over the distribution yields the number of particles in a unit volume. For spherical particles the parameters \( a \) and \( b \) correspond to the effective radius \( r_{\text{eff}} \) and to the effective variance \( \nu_{\text{eff}} \), respectively. Typical values of cirrus cloud size distributions for \( b \) are in the range between 0.1 and 0.5 (Evans, 1998; Heymsfield et al., 2002). In the following we take a fixed value of \( b = 0.25 \). We define the effective particle size \( r_{\text{eff}}(L) \) for an individual ice crystal as follows (Yang et al., 2005):

\[ r_{\text{eff}}(L) = \frac{3 V(L)}{4 A(L)} \]  

(A2)

Here \( L \) is the maximum dimension of a nonspherical ice crystal and \( A \) and \( V \) are the projected area and the volume of the particle, respectively. \( 2r_e(L) \) corresponds to the "effective distance", i.e., the representative distance a photon travels through an ice crystal without experiencing internal reflections and refraction (Mitchell et al., 1996). The effective radius of a size distribution is generally defined as:

\[ r_{\text{eff}} = \frac{3 \int_{L_{\text{min}}}^{L_{\text{max}}} V(L)n(L)\,dL}{4 \int_{L_{\text{min}}}^{L_{\text{max}}} A(L)n(L)\,dL} \]  

(A3)

In order to obtain bulk scattering properties which can be used for radiative transfer calculations, we pre-calculate bulk optical properties on a specified equidistant effective radius grid including values from 5 to 90 \( \mu \text{m} \) in steps of 5 \( \mu \text{m} \). Now using Eq. (A3) we iteratively find the parameter \( a \) of the size distribution which results in the desired effective radius. The bulk optical properties are then calculated by integration over the gamma distributions with the parameters \( b = 0.25 \) and the iteratively obtained \( a \) depending on the effective radius. libRadtran requires the extinction coefficient normalized to 1 g/m\(^3\) ice:

\[ \langle \beta_{\text{ext}}(r_{\text{eff}}) \rangle = \frac{\int_{L_{\text{min}}}^{L_{\text{max}}} A(L)Q_{\text{ext}}(L)n(L)\,dL}{\rho \int_{L_{\text{min}}}^{L_{\text{max}}} V(L)n(L)\,dL} \]  

(A4)

Here \( Q_{\text{ext}}(L) \) is the extinction efficiency, \( \rho \) is the density of ice, and \( n(L) \) is the gamma size distribution which corresponds to the effective radius \( r_{\text{eff}} \). The single scattering albedo \( \langle \omega_0 \rangle \) is calculated as follows:

\[ \langle \omega_0(r_{\text{eff}}) \rangle = \frac{\int_{L_{\text{min}}}^{L_{\text{max}}} A(L)\omega_0(L)Q_{\text{ext}}(L)n(L)\,dL}{\int_{L_{\text{min}}}^{L_{\text{max}}} A(L)Q_{\text{ext}}(L)n(L)\,dL} \]  

(A5)

Finally, libRadtran requires the phase matrix \( \langle P(r_{\text{eff}}) \rangle \), which is computed according to the following equation for each scattering angle \( \theta \) and for six matrix elements (denoted by index \( i \)) needed to describe the scattering process by randomly oriented nonspherical particles (see e.g. van de Hulst, 1981):

\[ \langle P(r_{\text{eff}}, i, \theta) \rangle = \frac{\int_{L_{\text{min}}}^{L_{\text{max}}} A(L)P(L, i, \theta)\omega_0(L)Q_{\text{ext}}(L)n(L)\,dL}{A(L)\int_{L_{\text{min}}}^{L_{\text{max}}} \omega_0(L)Q_{\text{ext}}(L)n(L)\,dL} \]  

(A6)

Optical properties for a general habit mixture \( q_{\text{hm}} \) have also been calculated for the hey parameterization following the mixing "recipe" suggested by Baum et al. (2005b).

Appendix B

Description of TZS solver

This solver is based on the zero scattering approximation and can be used to calculate clear sky or "black cloud" radiances at the top of the atmosphere (TOA) in the thermal spectral range. Without scattering the formal solution of the radiative transfer equation for the upward intensity (radiance) at TOA \( I_{\nu}(\tau = 0, \mu, \phi) \) at a given frequency \( \nu \) reduces to

\[ I_{\nu}(\tau = 0, \mu, \phi) = I_{\nu}(\tau^*, \mu, \phi) \exp(-\tau^*/\mu) + \int_{0}^{\tau^*/\mu} \frac{d\tau}{\mu} B_{\nu}(\tau) \exp(-\tau/\mu) \]  

(B1)

Here we used the (vertical) absorption optical thickness \( \tau \) measured from top of atmosphere as the vertical coordinate such that \( \tau = 0 \) at TOA and \( \tau = \tau^* \) at the surface. Variables \( \mu \) and \( \phi \) denote the cosine of the zenith angle and the azimuth angle respectively. Planck’s function at a given frequency \( \nu \) is represented by \( B_{\nu}(\tau) \) and its temperature dependence is contained implicitly in \( \tau \).

The first term on the right hand side in Eq. B1 represents the contribution of the surface and the second one the contribution of the atmosphere. The surface contribution can be written as

\[ I_{\nu}(\tau^*, \mu, \phi) = \epsilon_s B_{\nu}(\tau^*) + \]  

\[ + 2(1-\epsilon_s) \int_{0}^{\frac{1}{\mu}} \int_{0}^{\tau^*/\mu} B_{\nu}(\tau) \exp(-\tau^*/\mu) d\tau d\mu \]  

(B2)

with the first term representing the emission of the surface \( (\epsilon_s=\text{surface emissivity}) \) and the second one the reflection at the surface of the radiation emitted by the atmosphere toward the surface. The factor 2 comes from the integration over the azimuth angle \( \phi \).

Under the approximation of Planck’s function \( B_{\nu}(\tau) \) as a piecewise linear function in \( \tau \) between two consecutive levels, both integrals can be solved as a function of the exponential integral \( Ei(x) = \int_{-\infty}^{x} e^{-y}/y \, dy \).
Acknowledgements. Numerous colleagues have contributed with software and comments to the package. We would like to thank K. Stamnes, W. Wiscombe, S.C. Tsay, and K. Jayaweera (disort), F. Evans (polradtran), S. Kato (correlated-k distribution), J.-M. Vandenberghhe, F. Hendrick, and M. V. Roozendael (sdisort), T. Charlock, Q. Fu, and F. Rose (Fu and Liou code), D. Kratz (AVHRR routines), B. A. Baum, P. Yang, L. Bi, H. Gang, J. Key, B. Reinhardt, and A. Gonzales (ice cloud optical properties), P. Ricchiazzi (LOWTRAN/SBDART gas absorption), M. Hess (OPAC aerosol database), W. Wiscombe, C. F. Bohren, and D. Huffman (Mie codes), M. Mishchenko (water reflectance matrix), O. Engelsen (implementation of ozone cross sections), the ARTS community and Franz Schreier (line-by-line models), J. Betcke (implementation of King Byrne equation). Thanks to all users for feedback and contributions, which helped to improve the software over the years. Thanks also to L. Scheck for providing the simulated satellite image shown in Sec. 11.2. Finally we thank two anonymous reviewers for their useful comments. Part of the libRadtran development was funded by ESA (ESASLight projects AO/1-5433/07/NL/HE, AO/1-6607/10/NL/LvH).
