Abstract

Global land cover is a key variable in the earth system with feedbacks on climate, biodiversity and natural resources. However, global land-cover datasets presently fall short of user needs in providing detailed spatial and thematic information that is consistently mapped over time and easily transferable to the requirements of earth system models. In 2009, the European Space Agency launched the Climate Change Initiative (CCI), with land cover (LC_CCI) as one of thirteen Essential Climate Variables targeted for research development. The LC_CCI was implemented in three phases, first responding to a survey of user needs, then developing a global, moderate resolution, land-cover dataset for three time periods, or epochs, 2000, 2005, and 2010, and the last phase resulting in a user-tool for converting land cover to plant functional type equivalents. Here we present the results of the LC_CCI project with a focus on the mapping approach used to convert the United Nations Land Cover Classification System to plant functional types (PFT). The translation was performed as part of consultative process among map producers and users and resulted in an open-source conversion tool. A comparison with existing PFT maps used by three-earth system modeling teams shows significant differences between the LC_CCI PFT dataset and those currently used in earth system models with likely consequences for modeling terrestrial biogeochemistry and land-atmosphere interactions. The main difference between the new LC_CCI product and PFT datasets used currently by three different dynamic global vegetation modeling teams is a reduction in high latitude grassland cover, a reduction in tropical tree cover, and an expansion in temperate forest cover in Europe. The LC_CCI tool is flexible for users to
Plant functional type classification

modify land cover to PFT conversions and will evolve as Phase 2 of the European Space Agency CCI program continues.
Plant functional type classification

Introduction

Terrestrial ecosystems are characterized by a wide variety of biomes covering arctic to tropical vegetation and extending over almost 150 million square kilometers, about 30% of the earth’s surface (Olson et al., 2001). Land surface features associated with terrestrial ecosystems vary greatly across the earth due to climate, soil and disturbance conditions. Some of these features, like Leaf Area Index (LAI), surface roughness and albedo exert a strong control on the exchange of biogeochemical fluxes, including carbon, water and nutrients, as well as energy fluxes between vegetation and the atmosphere (Bonan, 2008). These fluxes have an influence on multiple atmospheric processes that function over various temporal and spatial scales (Sellers et al., 1996). Because of the importance of land-cover feedbacks on climate, a detailed and accurate description of global vegetation types and their patterns is thus a key component in dynamic global vegetation models (DGVM) and earth system models (ESM), with relevance for both weather and climate prediction. Presently, there are several global datasets of land cover available for modeling purposes, including MODIS-based land cover (Friedl et al., 2010), GLC2000 (Bartholome and Belward, 2005), and GLOBCOVER (Arino et al., 2008). However, the current generation of global land-cover datasets provides little consistency in terms of time period of observations, spatial resolution, thematic resolution and accuracy standards. This presents various challenges for earth system modeling applications that require recent and consistent time series of land-cover and particular thematic information regarding land-cover categories (Giri et al., 2005; Herold et al., 2008; Neumann et al., 2007; Poulter et al., 2011; Wullschleger et al., 2014).
Plant functional type classification

To address these challenges, the European Space Agency established the Land Cover component of the Climate Change Initiative (LC_CCI) and surveyed the land-surface modeling community to define user requirements for developing a new global land-cover dataset (Bontemps et al., 2012; Herold et al., 2011; Hollmann et al., 2013). The LC_CCI addressed these data needs by implementing an improved approach for mapping moderate-resolution global land cover consistently through time using surface-reflectance from the MERIS and VEGETATION 1 and 2 sensors aboard ENVISAT and SPOT 4 and 5, respectively. The final LC_CCI product resulted in the development of three global land-cover datasets, one for each of three epochs (1998-2002, 2003-2007 and 2008-2012) using a spectral classification approach derived from that of GLOBCOVER (Arino et al., 2008), yet with improved algorithms (Radoux et al., 2014). More importantly, its implementation to multi-year and multi-sensor time series ensured temporal consistency across epochs (Bontemps et al., 2012). The LC_CCI land-cover maps depict the permanent features of the land surface by providing information on land-cover classes defined by the United Nations Land Cover Classification System (UNLCCS). It also delivers land surface seasonality products in response to the needs of the ESM and DGVM communities for dynamic information about land-surface processes (Bontemps et al., 2012). Land surface seasonality products provide for each pixel the climatology describing, on a weekly basis, seasonal dynamics of snow cover, vegetation “greenness” based on the normalized difference vegetation index and burned area. Of particular relevance to the needs of the ESM modeling community, the LC_CCI developed a framework to convert the categorical land-cover classes to the fractional area of plant functional types, available at various spatial scales relevant to the respective ESMs.
Plant functional type classification

Plant functional types, or PFTs, are a key feature of current generation ESMs and represent groupings of plant species that share similar structural, phenological, and physiological traits, and can be further distinguished by climate zone (Bonan et al., 2002). Typically, 5-15 PFTs are included in an earth system model simulation (Table 1), including natural and managed grasses with either C3 or C4 photosynthetic pathways, broadleaf or needleleaf trees with deciduous, evergreen or ‘raingreen’ phenology, and shrubs (Alton, 2011; Krinner et al., 2005; Sitch et al., 2003). The PFT concept was originally proposed as a non-phylogenetic classification system partly to reduce computational complexity of ESMs but also to maintain a feasible framework for hypothesis testing. For example, interpreting the outcome of interactions for 5-15 PFTs following a model simulation is much more tractable than interpreting interactions among the thousands of plant species found throughout the world. The PFT concept also provides a practical solution to the problem that many of the plant traits required to parameterize a model at a species level are difficult to obtain (Ustin and Gamon, 2010). Second generation DGVMs are currently addressing some of the limitations posed by the PFT concept as plant trait data become more widely available (Kattge et al., 2011), as model structure becomes more computationally efficient (Fisher et al., 2010), or as modeling concepts move toward adaptive trait rather than ‘fixed’ values (Pavlick et al., 2013; Scheiter and Higgins, 2009).

This paper describes the LC_CCI land-cover classification and presents a conversion scheme that ‘cross-walks’ the categorical UNLCCS land-cover classes to their PFT fractional equivalent. This work is one of several LC_CCI publications that have previously described the need for consistent land-cover mapping (Bontemps et al., 2012), the user-requirements (Tsendbazar et al., 2014), and the processing of remote sensing data (Radoux et al., 2014). Land-cover to PFT conversion is
Plant functional type classification

a complex task and until the mapping of plant functional traits at global scale becomes possible (i.e., via 'optical types', Ustin and Gamon, 2010), the cross-walking approach remains a viable alternative for generating vegetation requirements for ESM and DGVM modeling approaches (Bonan et al., 2002; Faroux et al., 2013; Gotangco Castillo et al., 2013; Jung et al., 2006; Lawrence et al., 2011; Lawrence and Chase, 2007; Poulter et al., 2011; Verant et al., 2004; Wullschleger et al., 2014). The LC_CCI conversion scheme described here provides users with a transparent methodology as well as the flexibility to modify the cross-walking approach to fit the needs of their study region. The conversion scheme has been derived as part of a consultative process among experts involved in deriving the land cover map data and three ESM modeling groups as part of Phase 1 of the project. With consensus for the thematic translation scheme, a conversion tool has been designed to spatially resample PFT fractions to various model grid formats common to the climate modeling community. The cross-walking table is expected to be periodically updated by the LC_CCI team, i.e., Phase 2 of LC_CCI began in 2014, and will be revised to include modifications and improvements related to the classification scheme and mapping procedure.

Methods

**LC_CCI Land Cover Mapping Scheme**

The LC_CCI combined spectral data from 300-m full and 1000-m reduced resolution MERIS surface reflectance (and SPOT-VEGETATION for the pre-MERIS era) to classify land cover into 22 Level 1 classes and 14 Level 2 sub-classes following the UN LCCS legend (Di Gregorio and Jansen, 2000). The whole archive of full and reduced resolution MERIS data, 2003-2012, was first pre-processed in a series of steps that include radiometric and geometric corrections, cloud
Plant functional type classification screening and atmospheric correction with aerosol retrieval before being merged to 7-day composites. An automated classification process, combining supervised and unsupervised algorithms, was then applied to the full time series to serve as a baseline to derive land-cover maps that were representative of three 5-year periods, referred to as epochs, for 2000 (1998-2002), 2005 (2003-2007) and 2010 (2008-2012). The classification process was achieved through back- and up-dating methods using the full resolution SPOT-VEGETATION and MERIS time series. The three global land-cover maps described all the terrestrial areas by 22 land cover classes explicitly defined by a set of classifiers according to the UNLCCS, each classifier referring to vegetation life form, leaf type and leaf longevity, flooding regime, non-vegetated cover types and artificiality. Inland open water bodies and coastlines were mapped using Wide Swath Mode, Image Mode at Medium-resolution (150 m) and Global Monitoring Image Mode (1 km) acquired by the Advanced Synthetic Aperture Radar (ASAR) sensor aboard ENVISAT satellite for a single period (2005-2010).

In addition to the land cover classification, the land surface seasonality products describe, for 1 km² rather than 300 meter resolution, the average behavior and the inter-annual variability of the seasonal normalized difference vegetation index (NDVI), the burned area, and the snow occurrence, computed over the 1998-2012 period. These seasonality products were spatially coherent with the land cover classification and were provided at weekly intervals averaged over this 15-year period and were based on existing independent products: SPOT-VEGETATION NDVI daily time series, MODIS burned area (MCD64A1), and MODIS snow cover (MOD10A2). All products are provided to users in NetCDF and geotiff file format referenced to Plate Carrée projection using the World Geodetic System (WGS 84) and are available from
Plant functional type classification

Cross-walking land cover to PFTs

The conversion of land cover classes to PFTs is a non-trivial task that is made more complicated by the fact that the number and description of PFTs are not standardized across DGVMs. In the past, land cover (and other) information has been used to derive PFT maps based on individual model PFT descriptions. The method used to convert the land cover to PFTs has not always been documented in detail for each model. The aim of the approach taken here was to develop a general framework that could easily be adapted to the specific PFT description of any individual model. In consultation with the three climate modeling teams engaged in the LC_CCI project, Laboratoire des Sciences du Climat et de l’Environnement (LSCE), Met Office Hadley Centre (MOHC) and Max Planck Institute for Meteorology (MPI), 10 PFT groups were defined based on their phenology (needleleaf or broadleaf, evergreen or deciduous), physiognomy (tree, shrub, or grass), and grassland management status (natural or managed). Three additional non-PFT classes were added for bare soil, water and snow/ice. The cross-walking methodology is based on the approach of Poulter et al. (2011) and assumes that each UNLCCS category could be split into one or more PFT classes according to the LC class description at the per pixel level (Table 2). For example, the ‘cropland’ UNLCCS land cover class was assigned as 100% managed grass, whereas the UNLCCS ‘tree cover, needleleaved evergreen, open (15-30%)’ class was assigned to 30% needleleaved evergreen, 5% broadleaved deciduous shrub, 5% needleleaved evergreen shrub, and 15% natural grass. Of note, wet tropical forest vegetation, mainly the UNLCCS class
Plant functional type classification

‘tree cover, broadleaved evergreen, closed to open (>15%)’, was assigned to the PFT categories of ‘broadleaf evergreen’ tree (90%) and deciduous (5%), evergreen shrub (5%) following observations that moist tropical forests tend to have indeterminate phenology rather than distinct periods of onset and offset (Borchert et al., 2002; Fontes et al., 1995; Reich and Borchert, 1984). The derivation of Table 2 was the result of consultative process among the producers of the land cover map and the three modeling groups that reached a consensus on the PFT fractions for each LCCS-defined land cover class. The aim of this process was to gain a fuller understanding of the methods behind, and implications of, the respective vegetation classifications (LC and PFT). For example, previous LC class descriptions have included “semi-deciduous” in the description of broadleaved evergreen trees, as in tropical rainforests in particular, phenological strategies of certain species result in more pronounced seasonal leaf dynamics. However, such subtle differences in functionality are not currently incorporated into DGVMs, and tropical rainforests are considered to be 100% evergreen. Thus, in the cross-walking table derived in this study, the relevant LC class was mapped only evergreen trees and shrubs (see LC class 50 in Table 2). Other issues that were discussed included how different vegetation types are treated within a grid cell for DGVMs and the lack of representation of over- and understory canopies, which both had implications for how to deal with mosaic and open-cover classes.

For the most part, the cross-walking approach followed the definitions of the UNLCCS classes, where fixed proportions of land cover were split using a one to one rule for the respective PFT categories, as described above. In cases where the UNLCCS class was defined by a large range of tree cover and with no upper bound, i.e., “>15%” (Table 2) the uncertainties in this conversion can be considered larger than compared with other categories. In these cases, the land cover
Plant functional type classification

Remote sensing team of experts provided the criteria for the conversion approach, taking into account their improved understanding of the constraints of DGVMs. The impact of these uncertainties on the final PFT fractions, and on the simulated variables, is beyond the scope of this study. Here we purely aim to properly document a new, generic method for mapping between LC classes and PFT fractions that can be used for all DGVMs. However, the issue of uncertainty in the cross-walking procedure is currently being investigated in Phase 2 of the LC_CCI project.

The LC_CCI conversion tool

The LC_CCI land cover and seasonality products are initially downloaded in full spatial resolution, i.e., 300-meter grid cells for land cover, and 1km grid cells for the seasonality products, at global extent in Plate Carrée projection. In order to fulfil a range of ESM requirements, the LC_CCI project team developed the LC_CCI user tool to allow users to adjust parameters of the LC products in a way that is suitable to their model set-up, including modifying the spatial resolution and converting the LC_CCI classes to fractional PFT area. The BEAM Earth Observation Toolbox and Development Platform, designed for visualization and analysis of ENVISAT products, was selected to provide the basis of the conversion software. A list of resampling resolution and coordinate system options are provided in Table 3. The coordinate re-projection and aggregation of the LC_CCI data uses slightly different resampling algorithms depending on whether the tool is used on the land-cover or seasonality products. The tool converts the original LC_CCI geotiff file to target files produced in NetCDF-4 format and following CF (Climate and Forecast) conventions, more commonly used in numerical modelling. The open-source BEAM tool (source code at https://github.com/bcdev) can be run independently using
either Windows or Unix-based operating systems and the compiled operational tool can be downloaded from http://maps.elie.ucl.ac.be/CCI/viewer/download.php.

Re-sampling algorithm for LC_CCI land cover

For the land cover classes, the resampling algorithm produces an aggregated LC_CCI dataset that in addition to the fractional area of each PFT, also includes the fractional area of each LC_CCI UNLCCS class, the majority (dominant) LC_CCI UNLCCS class, and the overall accuracy of the aggregated classification. The majority class $n$ is defined as the LC_CCI class which has the rank $n$ of sorted list of LC_CCI classes by fractional area in the target cell (see Figure 1). The number of majority classes computed is a parameter, which can be defined by user, so that the full number of LCCS classes can be reduced to a user-defined subset, i.e., the top 3. Each original, valid land, water, snow or ice pixel contributes to the final target cell according to its area percentage contribution. The accuracy is calculated by the median of the land cover classification probability values weighted by the fractional area.

Re-sampling algorithm for LC_CCI seasonality products

The aggregation of LC_CCI seasonality products is specific for NDVI (i.e., greenness), burned areas, and snow cover. In the case of the LC_CCI NDVI condition, the mean NDVI over all valid NDVI observations are included in the aggregated product. The burned area and snow cover LC_CCI products also contain 3 different layers: the proportion of area (in %) covered by burned or snow area, the average frequency of the burned area or snow area detected over the aggregated zone and the sum of all valid observations of burned or snow area. Similar to aggregation rules for land-cover, each original pixel contributes to the target cell according to its
Plant functional type classification

area percentage but the value of a pixel will only be considered if its value falls within its valid
range, i.e., zero to one for NDVI.

Extension to specific model needs

The LC_CCI tool provides users with a zero-order classification, that is, the PFT classes are
defined as broadly as possible so that users have the advantage to continue to aggregate to the
requirements of their model (Figure 2). For example, models that do not include shrub PFTs can
merge shrub and tree categories together to create a single woody PFT category. Modeling
groups that require climatic distinctions for PFTs, for example, temperate versus tropical versus
boreal types can use their own climate or biome datasets such as Koeppen-Geiger or Trewartha
ecological zones (Baker et al., 2010; Kottek, 2006; Peel et al., 2007) and define classification rules
based on temperature thresholds, for example (Poulter et al., 2011). Most models also require a
distinction between the C3 and C4 photosynthetic pathways for different grass species, where C4
is more common in warm and dry climates (Edwards et al., 2010; Still et al., 2003). The
photosynthetic biochemistry of C4 grasses is very different to C3 grasses and their distribution
can be mapped either according to climate (Poulter et al., 2011) or to some combination of
remote sensing, ground-based observations and ecosystem modeling (Still et al., 2003). The
LC_CCI managed grassland PFT category represents all non-irrigated, irrigated and pasture lands
and so drawing finer thematic distinctions between these must come from country or sub-
country statistics similar to downscaling work made by Hurtt et al. (2006), Klein Goldewijk
(1997) and others (Monfreda et al., 2008; Ramankutty and Foley, 1998).

Analysis and comparison to PFT maps
Plant functional type classification

For analysis and demonstration of the tool, we compare the LC_CCI PFTs with the original PFTs used by the Land Surface Model (LSM) components of the ESMs from the three modeling centers developing ORCHIDEE at LSCE (Krinner et al., 2005), JULES at MOHC (Clark et al., 2011; Cox et al., 2000; Pacifico et al., 2011), and JSBACH at MPI (Knorr, 2000; Pongratz et al., 2009; Reick et al., 2013). The original ORCHIDEE PFT map, based on 12 PFTs plus bare soil, has its origins in the Olson land cover dataset from the 1980’s (Olson et al., 1983) and the International Geosphere Biosphere Program (IGBP) DISCover dataset for the period 1992-93 (Loveland and Belward, 1997). This was implemented within ORCHIDEE using a look-up table approach to estimate PFT fractions (Verant et al., 2004). The JULES model also uses PFT distributions derived from the IGBP DISCover dataset to estimate fractional coverage of 5 PFTs and 4 non-vegetated surfaces (water, urban, snow/ice and bare soil). JSBACH uses original data from Wilson and Henderson-Sellers (1985) and continuous tree fractions from Defries (1999) to represent the distribution and abundance of 12 PFTs. The LC_CCI Epoch 2010 was converted to 0.5 degree resolution using the LC_CCI user tool and compared with the individual default model PFT maps to illustrate regional differences and biases between products and to provide a baseline of how the LC_CCI products may improve land surface model performance.

Results

Global summary of LC_CCI

The global land areas covered by the aggregated 0.5 degree LC_CCI PFT equivalents (Figure 3) are dominated by barren and bare soil (39 Mkm²), followed by forests (30 Mkm²), managed grasslands, croplands and pasture (25 Mkm²), natural grasslands (18 Mkm²), and shrublands (14 Mkm²). For comparison, the MODIS Collection 5 land cover product developed by Friedl et al.
Plant functional type classification

(2010), report for barren area 18 Mkm$^2$, forest and savanna at 49 Mkm$^2$, a shrubland area of 22 Mkm$^2$, and 12 Mkm$^2$ for croplands. With reference to the Food and Agriculture Organization (FAO) statistics, forest area is reported as 38 Mkm$^2$ (FAO and JRC, 2012), cropland area as approximately 15 Mkm$^2$ (Monfreda et al., 2008) and pasture lands of 28 Mkm$^2$ (Ramankutty et al., 2008). While part of the areal differences are explained by the spatial resolution between the moderate-resolution MODIS data (500m) in comparison to the 0.5-degree LC_CCI data, thematic differences introducing uncertainty in aggregating to forest, grassland, etc. classes, and factors stemming from different definitions of forest cover thresholds used to categorize forest land between the UNLCCS approach (10% cover) and the IGBP (60%) approach used for MODIS. In addition, the UNLCCS to PFT conversion approach considers assumptions related to plant community level variability, and so a bare soil fraction is introduced during the conversion (see Table 3) increasing its global area and partially explaining the difference with MODIS land cover.

Comparison with original PFT maps

Differences between the LC_CCI PFT datasets and the original PFT datasets were specific for each ESM (Figure 4) largely because the original reference data were different per modeling group. Another challenge was that different PFT classification schemes were used for each model (Table 1), introducing further aggregation uncertainties in the comparison between LC_CCI and the original PFT data.

For all modeling teams, grasslands PFT distributions showed the largest changes, with significant reductions in northern latitudes for ORCHIDEE and JULES (Figure 6). For ORCHIDEE, the grassland PFT reductions were associated with an increase in bare soil, together with a shift
Plant functional type classification

from C3 grasses to (boreal) forest in the mid-to-high latitudes (Figure 5). Agricultural PFTs, not included in JULES, were similar for the original ORCHIDEE and LC_CCI inputs at regional scales, but showed increases in tropical regions where deforestation activities were high, e.g., the Brazilian arc of deforestation region. JSBACH generally had a reduction in cropland area, especially over North America and the North African arid regions.

Over arid regions, in comparison to the original PFT map, JULES decreased in C4 grasses over Australia, with an associated increase in the fractional cover of shrubs and bare soil. In the Sahel, apparent differences in the definition of natural and managed C4 grass account for differences found between ORCHIDEE and JSBACH. The inclusion of the LC_CCI product resulted in a large increase in the C4 grass fraction over the Sahel in ORCHIDEE, whereas no significant change in the C4 grass fraction has been found over these areas for JSBACH. Instead, an increase in C4 crops was found over the Sahel for JSBACH. Since the JSBACH conversion also accounts for pasture, this difference may be well the result of the pasture definition, which is a weighted part of all herbaceous PFTs. This also partly explains why the JSBACH C4 pasture PFT decreases exactly in the same areas where the C4 crops increase due to the use of the LC_CCI data. In JULES, the C4 types over Sahel shift to bare soil.

In the tropics, reductions in broadleaved tropical tree cover were largely consistent across all 3 ESMs, although increases in broadleaf forest area were found for some parts of African Congo Basin for JULES (Figure 6). Needleleaved forest area increased compared to the reference dataset for both JULES and JSBACH for boreal Europe and Australia (shrubland PFTs). The increase in needleleaved PFTs in boreal Europe was partially associated with a decrease in
Plant functional type classification

broadleaves (Figure 6a and 6b) for all three models, but also a decrease in natural grassland cover.

Discussion

Advantages of the LC_CCI for ESM modeling

The LC_CCI approach provides the ESM modeling community with a flexible tool for using up-to-date land-cover information consistently provided over time. Following the requests of the user survey, the land-cover dataset is available across multiple spatial domains, conforms to standard file formats used in numerical models, and includes information on classification confidence levels for the land cover classes and resulting PFT fractions. The standardized conversion tool provides users with a consistent documented approach for aggregating land cover classes and thus overcomes limitations associated with consensus approaches, for example (Tuanmu and Jetz, 2014). Of particular importance is that the multi-temporal LC_CCI mapping approach facilitated more accurate mapping leading to improved remote sensing observations of deforested areas in the tropics, the treeline-tundra boundary in the high latitudes, and better distinctions between managed and non-managed grasslands in Africa. Additionally, the SAR-based water bodies and coastline delineation helped to standardize the physical boundaries between terrestrial and water systems for all models. Using this standardized PFT mapping approach for ESMs can be expected to reduce model ensemble uncertainty as attempted by recent inter-model comparison efforts (Huntzinger et al., 2013).

Opportunities for Phase 2
Plant functional type classification

During Phase 1 of the LC_CCI project (2011-2014) several limitations of the conversion scheme and tool were recognized and have been targeted for improvement in Phase 2, where improvements to the land cover thematic classes and to the conversion scheme will be made. For example, in the high latitudes, a reduction in grassland fractional cover was observed with the LC_CCI product for all models, and on further investigation, it was recognized that a better representation of lichens and moss vegetation (Class 140, Table 3) would be an improvement for the Sparse Vegetation category (Class 150), especially in the high latitudes. Conversion of high-latitude land cover classes to PFT equivalents has been a challenge in several recent regional studies (Ottlé et al., 2013; Wullschleger et al., 2014) where discriminating spectrally between shrubs and trees, or grass and non-vascular plant species, remains difficult. Accurate mapping of high-latitude vegetation can be particularly important for modeling wildfire (Yue et al., 2014) where the spread of tundra fire is sensitive to fuel loading. In the tropics, the seasonal cycle of forest canopies continues to be a contentious issue (Morton et al., 2014; Myneni et al., 2007; Poulter and Cramer, 2009; Ryan et al., 2014) with the binary distinction between evergreen and deciduous phenology proving to be overly-simplistic where semi-deciduous traits are perhaps more appropriate (Borchert et al., 2002) and thus the development of tropical phenology traits that correspond to recent observations is a high priority (Bi et al., 2015). More specifically, Phase 2 will target i) improved thematic accuracy with a specific focus on transition areas (e.g. grassland-sparse vegetation-bare soil, tree-shrub-grassland) and the distinction between C3 and C4 grasses, ii) create a historical land cover time series to cover the 1990s using 1km AVHRR NDVI surface reflectances, iii) include more detailed change detection, with more classes, i.e., IPCC land categories (forests, agriculture, grassland, settlement, wetland, other land) as targets, and iv) deliver an albedo and/or LAI seasonality product.
Plant functional type classification

Physiological traits such as nitrogen fixation and different photosynthetic pathways, C3, C4 or Crassulacean Acid Metabolism (CAM), are presently not detectable from surface reflectance values, and so broad climate-based assumptions must be made to split into these groups. These assumptions can lead to large uncertainties that can impact a chain of ecosystem processes and land surface properties. While the LC_CCI dataset provides updated information on inland water bodies, the seasonality of water bodies and wetlands is yet to be represented and only considered in radar based surveys (Schroeder et al., In preparation). Finally, the existing UNLCCS land-cover classes currently do not include pastures whereas the importance of grazing on biogeochemical cycling is becoming increasingly recognized (Foley et al., 2005). Instead, pastures are currently mapped as croplands or grasslands according to their degree of management. Better thematic discrimination between these 3 classes would clearly improve the carbon cycle modeling as agriculture, in the broadest sense, is a significant contributor to land degradation and anthropogenic global greenhouse gas emissions (Haberl et al., 2007). Earth observation products are generally limited in to mapping land surface structural properties rather than functional one, and model-data fusion approaches can help reconcile problems that might arise from this limitation, especially in the case of grassland systems which may be managed or unmanaged, or may have different photosynthetic pathways. Nevertheless, remote sensing of land management categories remains a challenging task since existing classification approaches have yet to demonstrate an ability to capture the whole range of rangelands and crops diversity at global scale.

Earth System Modeling challenges
Plant functional type classification

Updating PFT datasets used in ESMs will clearly lead to improvements in the realism of the patterns of biogeography and have important feedbacks on simulating ecosystem processes and interactions with the atmosphere. Available PFT datasets used in ESMs remain outdated, using land cover information from the 1980s mainly because of a lack of tools available for cross-walking land cover to PFTs. The LC_CCI scheme and tool fills a critical data need for improving the representation of carbon, water and energy cycles being developed by the modeling community, however, extensive model benchmarking and calibration activities may now be necessary before the new PFT datasets result in model improvement. For example, model processes may be calibrated to some extent to produce performance metrics under outdated land cover information, and thus a range of benchmarks should be considered when transitioning to new PFT information.

Summary

The LC_CCI has made significant progress in responding to the ESM community data needs (Tsendbazar et al., 2014). These include:

- New land-cover classifications for 3 Epochs using consistent algorithms and based on the UNLCCS system.
- A user-friendly tool that can map the UNLCCS classes into user-defined PFT classes and at most grid resolutions used by the ESM community.
- Seasonality products describing average weekly conditions for burned area, NDVI and snow cover.
- Confidence information for each of the UNLCCS classes and a median estimate for the converted PFT legend.
Plant functional type classification

The UNLCCS-PFT conversion tool and the land cover products will continue to be improved during Phase 2 of the LC_CCI with updates made periodically and described at http://www.esa-landcover-cci.org.

Acknowledgements

The LC_CCI project was funded by the European Space Agency Climate Change Initiative Phase 1. The authors appreciate the support and comments from Frank Martin Seifert, Vasileos Kalogirou and Fabrizio Ramoino.

Figure 2: The LC_CCI land cover conversion tool processing chain requires converting the thematic legend and resampling the grid resolution to user defined PFT and coordinate system. Independent of the LC_CCI tool, users can append climate classes to the PFT aggregation.
Plant functional type classification

Figure 3: Fractional coverage of plant functional types, at 0.5-degree spatial resolution, calculated from original 300-meter LC_CCI dataset, epoch 2008-2012, using the LC_CCI conversion tool.
Plant functional type classification

Figure 4: Global PFT coverage comparing the LC_CCI and original datasets for a) ORCHIDEE, b) JULES, and c) JSBACH. Where ‘Br’ is broadleaf, ‘Ne’ is needleleaf, ‘Ev’ is evergreen, ‘De’ is deciduous, ‘ManGr’ is managed grassland, ‘NatGr’ is natural grassland, and ‘barren’ includes bare soil or ice. Note JSBACH has no bare soil category.
Figure 5: Difference in fractional coverage between the LC_CCI (epoch 2008-2012) and original ORCHIDEE PFT dataset, based on Olson et al. (1983).
Figure 6: Regional correlations between the original ESM PFT coverage and the LC_CCI, epoch 2008-2012, coverage for a) broadleaved trees, b) needleleaved trees, c) natural grasslands, and d) managed grasslands. The regions follow the TRANSCOM Experiment biome boundary definitions, which partition terrestrial ecosystems into 13 regions of similar vegetation (see Appendix 1).
Plant functional type classification

Appendix 1: TRANSCOM experiment biome boundaries from Gurney et al. (2002). The codes from Figure 6 are Boreal North America (NAmBO), Temperate North America (NAmTE), Tropical South America (SAmTR), Temperate South America (SAmTE), North Africa (NAf), South Africa (SAf), Boreal Eurasia (EuBO), Temperate Eurasia (EuTE), Tropical Asia (AsTR), Australia (AUST), Europe (EURO), Arid North Africa (NAfarid), Arid South Africa (SAfarid).
