Abstract. This study suggests a new modeling framework using a hybrid Lagrangian-Eulerian based modeling tool (the Screening Trajectory Ozone Prediction System, STOPS) for a prediction of an Asian dust event in Korea. The new version of STOPS (v1.5) has been implemented into the Community Multi-scale Air Quality (CMAQ) model version 5.0.2. The STOPS modeling system is a moving nest (Lagrangian approach) between the source and the receptor inside the host Eulerian CMAQ model. The proposed model generates simulation results that are relatively consistent with those of CMAQ but within a comparatively shorter computational time period. We find that standard CMAQ generally underestimates PM₁₀ concentrations during the simulation period (February 2015) and fails to capture PM₁₀ peaks during Asian dust events (22-24 February, 2015). The underestimated PM₁₀ concentration is very likely due to missing dust emissions in CMAQ rather than incorrectly simulated meteorology as the model meteorology agrees well with the observations. To improve the underestimated PM₁₀ results from CMAQ, we used the STOPS model with constrained PM concentrations based on aerosol optical depth (AOD) data from Geostationary Ocean Color Imager (GOCI), reflecting real-time initial and boundary conditions of dust particles near the Korean Peninsula. The simulated PM₁₀ from the STOPS simulations were improved significantly and closely matched to surface observations. With additional verification of the capabilities of the methodology on emission estimations and more STOPS simulations for various time periods, STOPS model could prove to be a useful tool not just for the
predictions of Asian dust but also for other unexpected events such as wildfires and upset emissions events.

1 Introduction

Particulate matter (PM) is one of the key air pollutants in the lower atmosphere. Numerous studies have reported its adverse effects on human health and the environment (Park et al., 2005; Heo et al., 2009; Jeon et al., 2015). Extreme levels of PM and the frequent occurrence of high PM events in the East Asia region have become a major social issue, particularly in South Korea (Korea, hereafter). This is because the region is geographically downwind from China and several desert areas, which are the source of significant emissions. Dust emissions from Mongolia and the Gobi Desert (Chun et al., 2001; Kim, 2008; Heo et al., 2009) cause extraordinarily severe yellow sand storms that often cover the entire sky over Korea during the spring and late winter. These result in the reduced visibility (Chun et al., 2001) and increased mortality due to cardiovascular and respiratory diseases (Kwon et al., 2002), and their adverse effects are more evident in cities closer to source regions of the Asian dust (Kashima et al., 2016).

In response to the problems resulting from Asian dust, the Ministry of Environment of Korea has undertaken PM$_{2.5}$ and PM$_{10}$ forecasting since 2015 to prevent possible harm caused by high PM concentrations; but the forecasting, however, sometimes fails to capture high-level PM events. Accurate PM forecasting is challenging because of the complicated physical and chemical properties of PM and uncertainties in meteorology and emissions (Gelencser et al., 2007; Kim et al., 2008; Tie et al., 2009).

A number of modeling studies have shown the important role of meteorology in PM (Pai et al., 2000; Otte, 2008a; Otte, 2008b), and some have suggested a variety of optimization techniques for enhancing the accuracy of meteorology (Ngan et al., 2012; Lee et al., 2011b; Choi et al., 2012; Jeon et al., 2014; Jeon et al., 2015; Li et al., 2016). Additionally, accurate and updated emission inventories are essential to more accurate PM forecasting. Several studies have used anthropogenic emissions inventories for the Asia domain, such as the International Chemical Transport Experiment - Phase B (INTEX-B) emissions inventory in 2006 and a mosaic Asian anthropogenic emissions inventory in 2010 (MIX) for reliable model performance (Zhang et al., 2009; Zhao et al., 2012; Li et al., 2015). However, the use of the optimized meteorology and the most recent emissions inventory as input data for PM simulations can provide accurate forecasting results for only “normal” time periods, not “upset” events such as Asian dust. This problem is further exacerbated because of the high uncertainty in dust emissions.

To address this issue, the intent of this study is to introduce a modeling tool for PM simulation that can be used in conjunction with the Community Multi-scale Air Quality (CMAQ) model (Byun and Schere, 2006) to more accurately predict PM concentrations, using an Asian dust-storm event as a case-
study. We apply a hybrid Eulerian-Lagrangian model, the Screening Trajectory Ozone Prediction System (STOPS), to simulate PM in the East Asia region. The model set-up includes a moving nest domain between the source and the receptor inside the host CMAQ structure. STOPS provides simulation results similar to those of CMAQ, but it does so much faster than the full CMAQ modeling system. Additional details of the original version of STOPS (v1.0) and its effectiveness for regional air quality simulations are explained by Czader et al. (2015). However, since STOPS v1.0 was based on CMAQ v4.4, it is incompatible for recent PM simulations due to outdated modules and chemical mechanisms. Hence, we have implemented a new version of STOPS (v1.5) into CMAQ v5.0.2, which can be utilized with recent emissions inventories, improved chemical mechanisms and useful analyzing tools for the better simulation of Asian dust events.

The primary purpose of this study is to characterize underestimated PM concentrations by standard CMAQ and to determine the primary reason why CMAQ does not accurately capture PM peaks, during the Asian dust events. We introduce a new modeling framework using STOPS as an alternative to full CMAQ modeling for the prediction of severe dust storms over the Korean Peninsula. We utilize STOPS for PM modeling and constrain PM concentrations using real-time satellite data from the Geostationary Ocean Color Imager (GOCI) sensor that allow STOPS to take into account the mostly updated input data (e.g., initial and boundary conditions and emission estimates) inside the modeling domain. We conduct several STOPS simulations using constrained PM concentrations and compare the results to corresponding surface observations to investigate whether the constrained PM concentrations produce accurate PM simulations. We ultimately conclude by proposing the STOPS forecasting/modeling system as an effective tool for capturing severe dust events over East Asia, particularly in Korea.

2 Methodology

2.1 STOPS

STOPS is a hybrid Eulerian-Lagrangian-based modeling tool derived from the CMAQ model. As shown in Fig. 1, a small sub-domain of STOPS was configured inside the CMAQ domain and it moves along with the mean wind from CMAQ. Since STOPS inherits meteorological fields and initial and boundary conditions from a “host” CMAQ simulation, the movement of the STOPS domain is limited to the domain of the host CMAQ simulation. STOPS has the same vertical structure and simulates the same physical and chemical processes as CMAQ, except for the calculation of advection fluxes. CMAQ uses horizontal wind velocity (u and v) from WRF to calculate horizontal advection fluxes, but STOPS calculates the difference between a cell horizontal wind velocity and the mean horizontal velocity in STOPS domain (Czader et al., 2015), so it can consider the moving speed and direction of STOPS domain for the calculation of advection fluxes. Since the STOPS domain moves over time, the
horizontal velocity from WRF should be adjusted based on the movement of STOPS domain. The movement of the STOPS domain is determined by the layer-averaged horizontal wind in the center column from the bottom layer up to the top of planetary boundary layer (PBL), weighted by the layer thickness. The averages of the u and v components are calculated by the following equations (Eq. (1)-(2)):

\[
\bar{u} = \frac{1}{\sum_{L=1}^{PBLH} \Delta \sigma_F(L)} \sum_{L=1}^{PBLH} u_L \cdot \Delta \sigma_F(L)
\]

\[
\bar{v} = \frac{1}{\sum_{L=1}^{PBLH} \Delta \sigma_F(L)} \sum_{L=1}^{PBLH} v_L \cdot \Delta \sigma_F(L)
\]

where \( \sigma_F = 1 - \sigma \) and \( \sigma \) is the scaled air pressure in a sigma coordinate system (dimensionless) defined as:

\[
\sigma = \frac{(p - p_t)}{(p_s - p_t)}
\]

where \( p \), \( p_t \) and \( p_s \) denote air pressure at the current level and the top and surface levels of the model, respectively. Czader et al. (2015) present more details on the model and its applications. The first version of STOPS (v1.0) was based on CMAQ v4.4 (Czader et al., 2015), but in this study, it has been updated to v1.5, and implemented in CMAQ v5.0.2.

2.2. Modeling system

In this study, we configured the CMAQ (v5.0.2) model with a domain in grid resolution of 27 km \((174 \times 128)\) covering the northeastern part of Asia (Fig. 2), and with 27 vertical layers extending from the surface to 100 hPa. This CMAQ domain, which is slightly larger than standard domain for East Asia study suggested by the Clean Air Policy Modeling System (CAPMOS) (http://capmos.nier.go.kr/index.jsp) of the National Institute of Environmental Research (NIER) in Korea, covers more areas of Gobi Desert which is a major source of Asian dust.

Anthropogenic emissions for the CMAQ domain were obtained from the MIX emissions inventory in 2010 (Li et al., 2015). This inventory contains gridded \((0.25^\circ \times 0.25^\circ)\) emissions information for black carbon (BC), carbon monoxide (CO), carbon dioxide (CO\(_2\)), nitrogen oxides (NO\(_x\)), ammonia (NH\(_3\)), organic carbon (OC), fine and coarse particulate matter (PM\(_{2.5}\) and PM\(_{10}\)), sulfur dioxide (SO\(_2\)) and non-methane volatile organic compounds (NMVOC). To acquire high-resolution \((1 \text{ km} \times 1 \text{ km})\) anthropogenic emissions in Korea, this study also used the Clean Air Policy
Support System (CAPSS) emissions inventory in 2011 of NIER (Lee et al., 2011a). The CAPSS inventory contains area, line, and point sources of CO, NH₃, NOₓ, sulfur oxides (SOₓ), total suspended particles (TSP), PM₁₀, and VOC. The emissions for the CMAQ simulations were prepared by the Sparse Matrix Operator Kernel Emissions (SMOKE) model (Houyoux et al., 2000). The Carbon Bond chemical mechanism (CB05) (Yarwood et al., 2005) and the AERO6 aerosol module (Nolte et al., 2015) were used for gas-phase and aerosol chemical mechanisms respectively, and initial and boundary conditions were obtained from the standard CMAQ profile.

We simulated meteorological fields using the Weather Research and Forecast (WRF, v3.7) model (Skamarock et al., 2008) and used the 1°× 1° Final Operational Global Analysis (FNL) data of the National Centers for Environmental Prediction (NCEP) to determine the initial and boundary conditions. To improve the accuracy of meteorological fields, we adopted the optimized grid analysis nudging options suggested by Jeon et al. (2015) for the East Asia simulations.

The WRF-CMAQ simulations were conducted for the period of 21 January to 28 February in 2015, which included the first ten days for spin-up. Evaluations applied to the month of February and the three-day Asian dust event occurred during 22-24 February in 2015. During the event days, massive dust over the GOBI desert and Mongolia region was transported to the Korean Peninsula. This happened due to the southeastward wind resulting from high pressure over the Mongolia region and low pressure over the northeastern part of China (Fig. S1 in the supplementary document). The detailed options used for WRF and CMAQ simulations are listed in Table S1 and S2 in the supplementary document.

The configuration of the CMAQ sub-domain for the STOPS simulation consists of 61 × 61 horizontal grid cells that covers a portion of the Korean Peninsula and the Yellow Sea, and its initial position was near the northern part of the Yellow Sea (40° N, 121° E) (Fig. 2), the transporting pathway of Asian dust. The simulated PM₁₀ concentrations of standard STOPS during Asian dust events (22-24 February, 2015) closely agreed with those of CMAQ (Fig. S2 in the supplementary document). The correlation coefficients (R) for each day were 0.94, 0.96, and 0.97, indicating that the results from STOPS and CMAQ are significantly correlated. This reasonable consistency of STOPS and CMAQ results justifies the use of STOPS instead of CMAQ, in this study.

2.3 In-situ and satellite measurements

This study used surface observational data from the Air Quality Monitoring Station (AQMS) network operated by NIER. The network measures real-time air pollutant concentrations and provides hourly concentrations for CO, NO₂, O₃, PM₂.₅, PM₁₀, and SO₂. We gathered the measured PM₂.₅ and PM₁₀ data in 2015 from the AQMS network and while meteorological data were obtained from the Automatic
Weather System (AWS) network, operated by Korea Meteorological Administration (KMA). The following statistical parameters were used for the evaluation of the performance of WRF and CMAQ simulations: Index Of Agreement (IOA), Mean Bias Error (MBE) and Root Mean Square Error (RMSE). These are defined as:

\[
\text{IOA} = 1 - \frac{\sum_{i=1}^{N}(P_i - O_i)^2}{\sum_{i=1}^{N}(|P_i - \bar{P}| + |O_i - \bar{O}|)^2}
\]

\[
\text{MBE} = \frac{\sum_{i=1}^{N}(P_i - O_i)}{N}
\]

\[
\text{RMSE} = \sqrt{\frac{\sum_{i=1}^{N}(P_i - O_i)^2}{N}}
\]

where \(N\) is number of data points and \(P_i\) and \(O_i\) denote CMAQ-simulated and observed concentrations, respectively.

We also employed the aerosol optical depth (AOD), measured by a GOCI sensor from the geostationary orbit onboard the Communication Ocean and Meteorological Satellite (COMS). The GOCI level 1B (L1B) data provide hourly daylight spectral images (09:30-16:30 LST, 8 times a day) for East Asia. The spatial coverage extends to 2500 km \(\times\) 2500 km centered at 36° N, 130° E (Lee et al., 2010; Choi et al., 2016). The AOD at 550 nm with a 6 km resolution were obtained from GOCI L1B data, using a retrieval algorithm introduced by Choi et al. (2016). The GOCI-derived AOD data were used for constraining of PM concentrations and the model evaluation. For the evaluation of CMAQ simulated PM\(_{10}\), we converted the concentration units in CMAQ to AOD for a fair comparison of the results with GOCI. The aerosol properties from the CMAQ simulation (CMAQ-derived AOD) were obtained by the following equations (Eq. (4)-(6)), which were introduced by Roy et al. (2007) and have successfully been tested in East Asia (Song et al., 2008; Park et al., 2011):

\[
AOD_{\text{CMAQ}} = \sum_{i=1}^{N} (\sigma_{sp} + \sigma_{ap})_i \Delta Z_i 
\]
\[ \sigma_{sp} = (0.003)f_t(RH)[NH_4^+ + SO_4^- + NO_3^-] + (0.004)[OM] + (0.001)[FS] + (0.0006)[CM] \quad (5) \]

\[ \sigma_{ap} = (0.01)[LAC] \quad (6) \]

where \( i \) is the vertical layer number, \( \Delta Z \) is the layer thickness, and the brackets indicate mass concentrations in mg m\(^{-3}\) units. The OM, FS, CM and LAC denote mass concentrations of organic species, fine soil, coarse particles, and light-absorbing carbon, respectively. The specific scattering coefficients in the equations (i.e., 0.003, 0.004, 0.001, 0.0006, and 0.001) are represented in units of m\(^2\) mg\(^{-1}\). The \( f_t(RH) \), calculated by the method described by Song et al. (2008), denotes relative humidity based on the aerosol growth factor.

### 3 PM\(_{10}\) simulation results from standard CMAQ

#### 3.1 Comparison with surface measurement

We simulated PM\(_{10}\) concentrations by standard CMAQ and compared them with surface observational data obtained from the AQMS network of NIER in Korea. For this comparison, we selected 20 AQMS sites, evenly distributed in Korea (Fig. 2), and calculated mean PM\(_{10}\) concentrations at all of the sites. We do not present the results for PM\(_{2.5}\) because the simulated PM\(_{2.5}\) exhibited almost same temporal variation and lower concentrations to those of PM\(_{10}\). In addition, the coarse particles comprise a major portion of the total PM during the Asian dust period, as described by Chun et al. (2001). From the comparison shown in Fig. 3, the concentration of CMAQ-simulated PM\(_{10}\) was slightly underestimated, but its temporal variation showed reasonably close agreement with observation except for the Asian dust episode (22-24 February, 2015). The CMAQ failed to capture the high peaks of PM\(_{10}\) in the episode caused by the transport of massive dust from the Gobi Desert and Mongolia region.

As shown in Table 2, the performance of CMAQ simulation for the entire period (February 2015) was poor. For example, the high value of RMSE (78.03 \( \mu g \) m\(^{-3}\)), low value of IOA (0.36) and negative value of MBE (-39.94 \( \mu g \) m\(^{-3}\)) indicate that CMAQ underestimated PM\(_{10}\), and its temporal variation did not agree well with the observations. The calculated statistics for the period excluding the Asian dust episodes was much better than those for the entire period, as indicated in Table 2. The large differences in these findings clearly reveal that the performance of CMAQ is relatively accurate for the regular simulation period, but it is not for the Asian dust period. As shown in Fig. 4 and Table S3, meteorological fields such as temperature and wind speed in the receptor regions (Korea) showed close agreement with observations, even during the Asian dust period. It suggests that the underestimated PM\(_{10}\) concentration was likely due to the uncertainty in meteorology in the source regions (China and
Mongolia), and/or faulty estimation of dust emissions for the CMAQ simulation. We attributed the main reason for the PM$_{10}$ underestimation to poorly estimated dust emission because CMAQ showed poor performance only during the Asian dust period.

To enhance the performance of CMAQ for PM$_{10}$ simulations during the Asian dust period, we employed the in-line windblown dust module in CMAQ v5.0.2. The module calculates the vertical dust emission flux ($F$) by following formula described by Fu et al. (2014).

$$F = \sum_{i=1}^{M} \sum_{j=1}^{N} K \times A \times \frac{\rho}{g} \times S_i \times SEP \times u_* \times (u_*^2 - u_{*t_{i,j}}^2)$$

where $i$ and $j$ represent the type of erodible land and soil, $K$ is the ratio between vertical and horizontal flux, $A$ is the particle supply limitation, $\rho$ is the air density, $g$ is the gravitational constant, $S_i$ is the area of the dust source, SEP is the soil erodible potential, $u_*$ is the friction velocity, and $u_{*t_{i,j}}$ denotes the threshold friction velocity.

Interestingly, the employment of the in-line windblown dust module in CMAQ simulations did not provide discernible enhancement in PM$_{10}$ concentrations (Table 2) because of lower friction velocity than the threshold in the module during the simulation period (February 2015) (Table S4 in the supplementary document). Several studies have reported that the threshold friction velocity plays a key role in the calculation of dust emission flux because the threshold can determine the probability of the lifting of dust particles (Choi et al., 2008; Fu et al., 2014). This research also implies that more studies that enhance the capability of dust modules during the winter period should be performed.

### 3.2. Comparison with satellite-based observation

Figure 5 presents a comparison of time-averaged AOD derived from GOCI and CMAQ. For an unbiased comparison of AOD, we removed grid cells from GOCI data consisting of fewer than 15 pixels (i.e., bad pixels) because of cloud contamination; we also did not include the corresponding grid cells in CMAQ for our comparison. The GOCI-derived AOD shows several blank areas in the northern part of the Korean Peninsula, near the northeastern region of China, and in most regions of Japan because of the significantly high fraction of clouds over these areas. The horizontal features of the CMAQ-derived AOD were similar to those of the GOCI-derived AOD, but CMAQ overestimated the AOD near the southeastern part of China. On the other hand, compared to the GOCI-derived AOD, the CMAQ underestimated the AOD over the Yellow Sea and Korea. As mentioned in Sect. 3.1, CMAQ underestimated surface PM$_{10}$ concentrations in Korea. The CMAQ-derived AOD in Korea was also underestimated compared to GOCI-derived AOD, consistent with the surface measurements. These comparisons using the satellite and surface measurements indicated that the CMAQ was unable to capture the high levels of PM in Korea during the simulation period in this study (February 2015).
Hence, the discrepancy between CMAQ- and GOCI-derived AOD is likely due to uncertainty in emissions of PM precursors such SO$_2$, NO$_x$, and NH$_3$ (Jeon et al., 2015) and meteorology over source regions as discussed in Sect 3.1.

Compared to the GOCI-derived AOD, the CMAQ-derived AOD near the northern regions of the Korean Peninsula was underestimated. This underestimation may have resulted from the failure of CMAQ to simulate the Asian dust emissions and their transport to the Korean Peninsula on 22-24 February in 2015. The CMAQ-derived AOD was underestimated primarily in the moving pathway of the Asian dust (i.e., between the Gobi Desert (source area) and Korean Peninsula (receptor area)). As addressed in Sect. 3.1, the in-line windblown dust module in CMAQ failed to accurately estimate the dust emissions during the Asian dust period and it caused the model to underestimate AOD near the northern regions of the Korean Peninsula.

To further investigate the issue of underestimation of CMAQ during the period of Asian dust (22-24 February, 2015), we compared the GOCI- and CMAQ-derived AODs on each event day. Unfortunately, the comparison was available only on 22 February since the GOCI-derived AOD included a significantly high number of blank pixels on the other event days because of the high fraction of cloud cover. Figure 6 shows GOCI- and CMAQ-derived daily mean (09:30-16:30 LST) AODs on 22 February. The GOCI-derived AOD clearly showed massive dust near the northwestern regions of the Korean Peninsula and the eastern part of China and densely distributed dust particles over the Yellow Sea that were transported from the Gobi Desert. In contrast, CMAQ did not reproduce the high dust concentrations near the Korean Peninsula because of the failure in the estimation of dust emissions.

We concluded that CMAQ clearly underestimated PM$_{10}$ concentrations during the simulation period and failed to capture peaks during the Asian dust period starting on 22 February. Thus, we attempted to use STOPS for capturing the dust enhanced PM$_{10}$ in Korea (receptor region). We used the dust storm data temporarily detected by satellite measurements between the source and receptor regions as an input for the STOPS modeling. The following sections describe the details how STOPS was used for PM$_{10}$ forecasting.

4 Application of STOPS for PM$_{10}$ forecasting

Assuming the CMAQ PM$_{10}$ simulation results in this study were used for forecasting purposes, the severe dust events starting on 22 February in 2015 could not be predicted. Thus, to accurately forecast the transport of massive dust storm, we must take into account the most recent and accurate initial and boundary conditions and emissions. Figure 7 shows the GOCI-derived AOD on 21-22 February, when a dust storm was approaching Korea (receptor region). The massive dust storm was not evident from the GOCI-derived AOD on 21 February, but a center of the dust storm in the northwestern region of the Korean Peninsula was first seen at 10:30 LST on 22 February. Upon observation of the massive dust from the GOCI-derived AOD at 10:30 LST on 22 February, a new PM$_{10}$ forecasting using STOPS with
real-time AOD data can be performed in a short time (i.e. a few minutes) and the current forecasting results can be replaced by the results from the STOPS. For the new PM$_{10}$ forecasting using STOPS, we intended to use the GOCI-derived AOD as a new initial condition for PM$_{10}$ species. However, the approach does not fully consider continuous transport of dust from the source regions because the impact of the changed initial condition on the STOPS results would be diminished within a few hours. Thus, we used the GOCI-derived AOD as PM emissions for the STOPS forecasting to make the best use of the AOD data.

4.1 Satellite-adjusted PM concentrations

For the new PM$_{10}$ forecasting using STOPS, we first attempted to convert the GOCI-derived AOD to PM concentrations and directly add them to the simulated PM concentrations by STOPS. However, the sudden and rapid changes in PM concentration made the STOPS simulation unstable and they sometimes caused unexpected termination of STOPS runs due to overflow error. To resolve this problem, we regarded the GOCI-derived AOD as PM emissions and indirectly constrained the original PM concentrations by using the alternative emissions. In short, the GOCI-derived AOD was converted to emissions and used for the STOPS forecasting. We should note that the alternative emissions are not real, but the enhanced dust concentrations which are taking the form of emissions. We concluded this methodology could be an effective way to reflect the satellite measured AOD to CMAQ simulation without possible computational error.

As indicated in Fig. 7, the massive dust storm was first captured by the GOCI-derived AOD at 10:30 LST on 22 February in 2015, so we adjusted the standard emissions at a corresponding time based on the GOCI-derived AOD and used them for the STOPS forecasting. We should note that the AOD and the emissions rate are expressed in different units; the AOD is a unitless value, while the emission rate is expressed in units of grams per second (particles) or moles per second (gas-phase species); therefore, we employed a scaling factor to convert the AOD to the emissions rate. To find a reasonable scaling factor, we re-gridded the domain of the GOCI-derived AOD data so that it corresponded to the CMAQ domain and compared the AOD in each grid cell with corresponding emission rates of total PM in the MIX inventory (e.g., PM$_{10}$). We used only the grid cells with valid AODs (no missing values) and emission rate (> 0) for the comparison and then calculated the average ratio of the AOD to emissions rates. The calculated ratio was 1,884.49 g s$^{-1}$ for this case, indicating that the emissions rate of total PM inside the modeling domain was 1,884.49 times larger than the GOCI-derived AOD. It should be noted that the ratio cannot generally explain the relationship between AOD and emissions. Because the relationship is valid for only a particular domain (Fig. 2) and time (10:30 LST on 22 February, 2015), the ratio for each case should be recalculated.

For the unit conversion from the AOD to the emissions rate of total PM, we used the estimated ratio as a scaling factor and calculated the total PM emissions by the following equation (Eq. (8)):
\[ PM_{i,j} = AOD_{i,j} \times SF \] (8)

where \( PM_{i,j} \) and \( AOD_{i,j} \) represent the emission rates of total PM and GOCI-derived AOD in each grid cell, respectively. SF is the calculated scaling factor (1,884.49 g s\(^{-1}\)), which indicates the relationship between the AOD and the emissions rate.

For the STOPS simulation, we split the calculated \( PM_{i,j} \) into several specific species, including coarse and fine particles, used for the CB05-AERO6 chemical mechanism. In order to calculate the species distribution, we estimated the mass fractions of each PM species during the Asian dust events based on the findings in Kim et al. (2005) and Stone et al. (2011), which described the composition of measured PM during the Asian dust periods (Table 3). More than half of the \( PM_{i,j} \) was allocated to coarse particles (PMC) because they comprise a major percentage of Asian dust, as reported in several studies (Kim et al., 2003; Lee et al., 2004; Kim et al. 2005; Stone et al., 2011). The speciated PM emissions were injected into standard PM emissions in each grid cell. Based on the findings by Kim et al. (2010), the amounts of the alternative emissions were assumed to be distributed below the altitude of 3 km (1 to 11 vertical layers). The entire procedures of the new PM forecasting by STOPS using GOCI-derived AOD are briefly depicted in Fig. S3.

### 4.2 Enhanced PM\(_{10}\) forecasting using STOPS

We conducted a new PM\(_{10}\) forecasting run using STOPS with the constrained PM concentrations (by using alternative emissions) and examined the improvement in its accuracy over that of the standard CMAQ model. The STOPS forecasting covers one-day (24 hours), which began at 11:00 LST on 22 February in 2015 immediately following the massive dust first observed in the GOCI-derived AOD between the source and receptor regions.

Figure 8 shows the comparison of the PM\(_{10}\) concentration from CMAQ using standard emissions and STOPS using alternative emissions. The PM\(_{10}\) from standard CMAQ exhibited high concentrations over the eastern part of China, central Yellow Sea and northwestern part of the Korean Peninsula. By contrast, the constrained PM\(_{10}\) by the alternative emissions (Fig. S4 in the supplementary document) exhibited significantly increased concentration, particularly in the northwestern part of the Korean Peninsula (Fig. 8). The constrained PM\(_{10}\) concentration showed similar features as those of the GOCI-derived AOD, shown in Fig. 6-(a), implying that the dense dust attributed by Asian dust were accurately reflected in the STOPS forecasting.

We should note that the duration of the release of alternative emissions strongly affected the simulated PM\(_{10}\). Hence, it plays an important role in the STOPS forecasting, so we conducted four forecasting runs with different release durations (3hr, 6hr, 12hr, and 24hr) as shown in Fig. 9, and
compared all of the results with those of standard CMAQ and available PM$_{10}$ surface measurements. Figure 9 exhibits clear differences in the temporal variation of PM$_{10}$ resulting from the impact of the durations. As addressed in Sect. 3.1, the standard CMAQ run failed to capture the drastic increase in PM$_{10}$ concentrations on 22 February in 2015 because of the poor dust emission modeling in CMAQ. However, the STOPS forecasting showed significantly improved PM$_{10}$ results compared to standard CMAQ. The results indicated higher PM$_{10}$ concentrations than those of CMAQ, and they were much closer to observations.

Interestingly, Figure 9 shows that predicted PM$_{10}$ by STOPS with a duration of release of three hours (STOPS_E3) closely agreed with observations during the first three hours. However, the simulated PM$_{10}$ began to decrease immediately after the third hour, and the agreement with observations gradually worsened with time. The results of the other STOPS runs with different durations of release of 6, 12, and 24 hours (STOPS_E6, STOPS_E12 and STOPS_E24, respectively) were almost the same as those of STOPS_E3. In other words, the impact of the alternative emissions on the PM$_{10}$ prediction highly depends on the durations of emission release and the impact was gone after the release ended. STOPS_E24 represented the closest agreement with observations, implying that STOPS_E24 produced the greatest improvement in one-day PM$_{10}$ forecasting because of continuous emissions during the entire forecasting time (24 hours).

Despite its positive performance in one-day PM$_{10}$ forecasting, STOPS_E24 did not perfectly capture the high PM$_{10}$ concentrations during the Asian dust event. In fact, it underestimated the peak of observed PM$_{10}$, which may have resulted from uncertainty inherent in the methodology using AOD estimation. Direct conversion from the AOD to the alternative emissions rate using a scaling factor is challenging because it has not yet proven reliable by existing studies. Hence, the uncertainty inherent in unit conversion might have contributed to the inaccuracy of the emissions rate. In addition, the GOCI-derived AOD data contained missing data due to the cloud cover over the study area during the event on 22 February, and as a consequence, it did not accurately represent the distribution of transported Asian dust. The most probable reason for the underestimated PM$_{10}$ simulated by STOPS was that the alternative emissions during the first time step (11:00 LST on 22 February, 2015) were subsequently used for all of the time steps without accounting for spatiotemporal variations. Since the horizontal and vertical distributions of the Asian dust changed with time, the alternative emissions in the first time step did not accurately represent the varied dust distribution in the next time step. The uncertainty with regard to the alternative emissions increases with time. The STOPS_E24-predicted PM$_{10}$ concentrations showed close agreement with observations during the first six hours (Fig. 9), but error gradually widened with time. However, as observation in later hours cannot be reflected at the beginning of forecasting, such a problem is inevitable in a forecasting mode. Thus, repeated forecasting for short time periods (e.g., six hours) with the variable alternative emissions could possibly provide more accurate PM$_{10}$ results for the Asian dust events. STOPS would be very useful for repeated PM$_{10}$ forecasting because of its remarkably short simulation time (a few minutes).
To verify the horizontal distribution of PM$_{10}$ resulting from the effect of constrained PM, we compared the simulated surface PM$_{10}$ concentrations from the STOPS forecasting to those from standard CMAQ. Figure 10 shows the horizontal distribution of surface PM$_{10}$ concentrations inside the STOPS domain simulated by standard CMAQ and STOPS_E24, which indicates the most accurate one-day forecasting results of all the STOPS simulations (from Fig. 9). The location of the STOPS domain moved slightly toward a southeasterly direction according to the changed mean wind in the domain. In the first time step (0 hr, 11:00 LST, 22 February), STOPS_E24 showed the same PM$_{10}$ distribution as standard CMAQ because the initial condition for the STOPS simulation was provided by the standard CMAQ. After eight hours, the PM$_{10}$ concentration from STOPS_E24 differed from that of the standard CMAQ owing to the effect of the alternative emissions by the GOCI-derived AOD. After sixteen and twenty four hours, the difference became more pronounced. Results of standard CMAQ did not show a high level of PM$_{10}$, but those of STOPS_E24 showed a PM$_{10}$ concentration of at least 100 $\mu$g m$^{-3}$ near the Korean Peninsula. Specifically, they showed extremely high PM$_{10}$ concentrations of over 1,500 $\mu$g m$^{-3}$ in the northwestern part of the Korean Peninsula. Figure 7 (10:30 LST on 22) indicates massive dust over that area from the GOCI-derived AOD consistent with the enhanced PM$_{10}$ concentrations. The massive dust over the region were transported to Korea and led to significantly enhanced levels of PM$_{10}$. The horizontal distributions of PM$_{10}$ at higher vertical levels up to 3 km showed similar features at the surface layer because the alternative emissions were evenly distributed below that level.

Overall, even with the uncertainties addressed above, the massive dust storm near the Korean Peninsula on an Asian dust day was reasonably reproduced by the STOPS forecasting with using PM emissions constrained by GOCI-derived AOD. These results indicate that the STOPS could possibly be used for new PM$_{10}$ forecasting with real-time constraints of PM concentration and this methodology should enhance the performance of PM$_{10}$ forecasting and modeling.

5 Summary

This study introduced a new modeling framework using a hybrid Eulerian-Lagrangian model (called STOPS) that showed almost the same performance as CMAQ, but used a shorter simulation run-time. STOPS v1.5 has been implemented into CMAQ v5.0.2 for PM$_{10}$ simulations over the East Asia during Asian dust events, and we investigated possibility of using STOPS to enhance the accuracy of PM$_{10}$ forecasting. During the entire simulation period (February 2015), the standard CMAQ underestimated PM$_{10}$ concentrations compared to surface observations and failed to capture the PM$_{10}$ peaks of Asian dust events (22-24 February, 2015). With reasonable meteorological input, the under-prediction of PM$_{10}$ concentration was mainly due to the inaccurate estimation of dust emissions during this period used in CMAQ. We also evaluated the horizontal feature of CMAQ simulated PM$_{10}$ using satellite-observed
The PM$_{10}$ results from the standard CMAQ run were compared to those of the GOCI-derived AOD and the results indicated that the standard CMAQ barely captured the transported dust from the Gobi Desert to the Korean Peninsula during the Asian dust events.

For more accurate PM$_{10}$ prediction, we used the STOPS model and conducted several simulations using constrained PM concentrations (by using alternative emissions) based on the GOCI-derived AOD, which reflected the most recent initial and boundary conditions near the Korean Peninsula. The STOPS simulations showed higher PM$_{10}$ concentrations than the standard CMAQ and indicated clear dependence on the duration of the alternative emission release. The STOPS simulations showed reasonable PM$_{10}$ concentrations close to observational data, but they did not capture the peak during the Asian dust events because of uncertainty in the methodology used for the constraining PM concentrations. The direct conversion from AOD to emissions using a scaling factor was challenging because it has not yet proven reliable by existing studies. In addition, the GOCI-derived AOD data were missing many values because of the high fraction of clouds cover during the event and consequently, it did not accurately reflect the massive dust storm on the Asian dust day.

Overall, STOPS reasonably reproduced the high level of PM$_{10}$ over the Korean Peninsula during the Asian dust event with constrained PM concentrations using satellite measurements. Although STOPS indicated significantly high PM$_{10}$ enhancement for the episode, it still requires improvement before its results can be generalized. Thus, we should direct our study toward additional verification of the methodology regarding unit conversion (e.g. possible nonlinearities) and numerous sensitivity simulations for different cases to determine the optimal duration of the release of the alternative emissions. The results of this study are an ideal starting point for such studies.

The ultimate goal of this study was to suggest an effective tool for successive PM$_{10}$ forecasting and modeling over the East Asia, and the results clearly showed the reliability and various advantages of STOPS modeling. Therefore, because of its reliable performance with remarkably high computation efficiency, the STOPS model could prove to be a highly useful tool for enhancing dust forecasting/modeling performance over East Asia. Further, the benefit of STOPS modeling could be generalized to the forecasting and modeling of unexpected events such as wildfires and upset oil and emissions events.

**Code availability**

The STOPS v1.5 source code can be obtained by contacting the corresponding author at ychoi6@uh.edu.

**Acknowledgments**

This study was partially supported by funding from the Ministry of Environment of Korea (NIER-1900-1946-302-210). We thank the team members of GOCI and AQMS for the preparation of the remote
sensing data and PM measurement data, respectively.
