Author Response to Interactive Comment by Anonymous Referee #1 on
"ORCHIDEE MICT-LEAK(r5459), a global model for the production, transport and
transformation of dissolved organic carbon from Arctic permafrost regions, Part
1: Rationale, model description and simulation protocol" by Simon P. K. Bowring
et al.

Dear Anonymous Referee #1,

Thank you for taking the time to read and review our manuscript, and in doing so
providing such diligent and constructive commentary for its improvement, which we
hope we have been able to assimilate into its content to the greatest degree possible in
our responses, which follow below.

Specific Comments

Line 46: the "migration of permafrost line" really only makes sense on a map.
Perhaps rephrase.
Thank you for spotting this conceptually misleading description in our text. The phrase
has now been modified to
"... as the boundary between discontinuous and continuous permafrost migrates poleward
and toward the continental interior over time."

line 50: the authors pulled out some very high number, I don't know where this
came from. McGuire 2009 estimates a lateral flux of 80 Tg C and a net "arctic" land
sink of 600-800 Tg C. That makes the DOC component ~10% of NEP.

Again, thank you for spotting this, which indeed looks misleading, and comes from
taking a mix of upper and lower bounds for lateral flux and NEP, respectively. However,
we can't find the 600-800 Tg C /yr. sink you refer to in the reference cited. Referring to
McGuire et al (2009) Table 2, the inversion-based terrestrial sink from Rödenbeck et al
(2003) is 400 Tg C/yr, that from Baker et al (2006) is 190 Tg C/yr, and that from Gurney
et al. (2003) is 230 Tg C/yr. Because these estimates exclude the European Arctic,
McGuire estimates that the 'true amount is 'less than' 0.5 Pg C/yr which, given the
uncertainty range from the inversion studies, means that he accepts the range of the net
CO2 sink as being 0-800 Tg C/yr. In Table 6 of McGuire et al., indeed the lateral carbon
flux is 39 Tg C/yr excluding DIC and 83 Tg C/yr with it.

In our manuscript text body, we write that "the yearly lateral flux of carbon from soils
to running waters may amount to ~40% of net ecosystem carbon exchange". This
implies the total lateral carbon flux, and not the DOC. Thus, from a mid-point of 400
Tg C/yr from the above-mentioned 0-800 Tg C/yr, we re-write the sentence as follows:

"[..] the yearly lateral flux of carbon from soils to running waters may amount to about a
fifth of net ecosystem carbon exchange (~400 Tg C yr^-1), about ~40% of which may be
contributed by DOC (McGuire et al., 2009). Excluding the dissolved inorganic carbon
component of this flux, as well as dissolved CO2 input from soils, the vast majority (85%) of
riverine organic carbon discharge to the Arctic Ocean occurs as dissolved organic carbon
(DOC), as described in (e.g.) Suzuki et al. (2006)."
155-156: I think these numbers need to be double checked. The point of this paragraph could be clearer.

The numbers have been double-checked and are as reported in McGuire et al. (2009), but now distinguish between total evasion and the water bodies from which these occur as follows:

"CO₂ evasion rates from Arctic inland waters (Fig. 1j,e,m), which include both lakes and rivers, are estimated to be 40-84 TgC yr⁻¹ (McGuire et al., 2009), of which 15-30 TgC yr⁻¹ or one-third of the total inland evasion flux, is thought to come from rivers. However, a recent geo-statistically determined estimate of boreal lake annual emissions alone now stands at 74-347 TgC yr⁻¹ (Hastie et al., 2018), potentially lowering the riverine fraction of total CO₂ evasion. These numbers should be compared with estimates of Pan Arctic DOC discharge from rivers of 25-36 TgC yr⁻¹ (Holmes et al., 2012; Raymond et al., 2007)."

249-254: This paragraph is confusing. The points could be expanded and clarified

"However numerous improvements in code performance and process additions post-dating these publications have been included in this code. Furthermore, novel processes included in neither of these two core models are added to MICT-L, such as the diffusion of DOC through the soil column to represent its turbation and preferential stabilisation at depth in the soil, as described in Section 2.11."

265-274: This is quite confusing and makes what is new here unclear.

"Where these differences were so large as to prove a burden in excess of the scope of this first model version, such as the inclusion of the soil carbon spinup module, they were omitted from this first revision of MICT-L. The direction of the merge—such model was the base which incorporated code from the other—was from ORCHILEAK into MICT, given that the latter contains the bulk of the fundamental (high latitude) processes necessary for this merge."

289: This is the first mention of this site specifically, and it really comes out of nowhere. Consider introducing the site before this.
We agree with this observation, and have added in the following sentence at the end of the Introduction (line 264-267).

“The choice of the Lena River basin in Eastern Siberia as the watershed of study for model evaluation owes itself to its size, the presence of floodplains and mountain areas which allow us to test the model behavior for contrasting topography, the relatively low impact of damming on the river, given that ORCHIDEE only simulates undammed fluvial ‘natural flow’, and its mixture of continuous and discontinuous permafrost with tundra grassland in the north and boreal forests in the south, and is described in greater detail in Part 2 of this study.”

430: Typo 437: typo
Extra full-stop removed.

444-446: Confusing. This sounds like a lake or pond
The section you refer to is: “Further, in modelled frozen soils, a sharp decline in hydraulic conductivity is imposed by the physical barrier of ice filling the soil pores which retards the flow of water to depth in the soil, imposing a cap on drainage and thus potentially increasing runoff of water laterally, across the soil surface (Gouttevin et al., 2012). In doing so, frozen soil layers overlain by liquid soil moisture will experience enhanced residence times of water in the carbon-rich upper soil layers, potentially enriching their DOC load.”

This refers to the frozen vertical barrier imposed by soil freezing on hydrological transfer to deeper layers. This is why they are referred to as 'liquid soil moisture' as opposed to water body or some such, as it implies that water increases its residence time in a certain layer above the frozen portion, but does not remain static there nor 'pond' into a water body proper.

We have also added the clarification that frozen water in the form of thick ice wedges that are important for e.g. thermokarst formation, are not simulated by the present model formulation, e.g. ”Note that ice wedges, an important component of permafrost landscapes and their thaw processes, are not included in the current terrestrial representation, but have been previously simulated in other models (Lee et al., 2014)”.

In addition, we found some potentially misleading text in the following segment: "First, in the process of drainage DOC is able to percolate from one layer to another, through the entirety of the soil column, meaning that vertical transport is not solely determined by 11th layer concentrations, given that DOC can be continuously leached and transported over the whole soil column.”

We have adapted this section as follows:

“First, as it water percolates through the soil column, it carries DOC along from one layer to another through the entirety of the soil column, but this percolation is blocked when the soil is entirely frozen, i.e. it is assumed that all soil pores are filled with ice which blocks
percolation. This implies that DOC transport is not just determined by what enters from the
top but also by the below ground production from litter, the sorption and de-sorption to
and from particulate soil organic carbon in the soil column, its decomposition within the
soil column, and water vertical transport entraining DOC between the non-frozen soil
layers using the hydraulic conductivity calculated by the model as a function of soil texture,
soil carbon and time-dependent soil moisture (Guimberteau et al., 2018)."

474: typo
This has been corrected.

4780480: confusing
This refers to the following section of the manuscript: "The water residence time in each
reservoir depends on the nature of the reservoir (increasing residence time in the order
: stream < fast < slow reservoir). More generally, residence time decreases with the
steepness of topography, given by the product of a local topographic index and a
constant with decreasing values for the 'slow', 'fast' and 'stream' reservoirs."

To clarify this, we have shortened and increased the conciseness of the segment as
follows:
"More generally, residence time locally decreases with topographic slope and the grid-cell
length, used as a proxy for the main tributary length (Ducharne et al., 2003; Guimberteau
et al., 2012). This is done to reproduce the hydrological effects of geomorphological and
topographic factors in Manning's equation (Manning, 1891) and determines the time that
water and DOC remain in soils prior to entering the river network or groundwater."

In addition, to increase the readability of the subsection, descriptions of the hydrological
module in the paragraph preceding the segment you refer to are improved upon. The
original section reads: "The 'slow' water reservoir aggregates the soil drainage, i.e. the
vertical outflow from the 11th layer (2 m depth) of the soil column, effectively
representing 'shallow groundwater' storage. The 'fast' water reservoir aggregates
surface runoff simulated in the model, effectively representing overland hydrologic flow.
The 'slow' and 'fast' water reservoirs feed a delayed outflow to the 'stream' reservoir of
the adjacent sub-grid-unit in the downstream direction."

The model's hydrology routing scheme is indeed a complex system, and we use the same
terminology as that adopted by its architects cited to in the text, which in turn follow the
terminology given to these water reservoirs in the model code.

Thus we only try to make clearer the last sentence of the paragraph with the following
edit: "The 'slow' water reservoir aggregates the soil drainage, i.e. the vertical outflow from
the 11th layer (2 m depth) of the soil column, effectively representing 'shallow
groundwater' transport and storage. The 'fast' water reservoir aggregates surface runoff
simulated in the model, effectively representing overland hydrologic flow. The 'slow' and
'fast' water reservoirs feed a delayed outflow to the 'stream' reservoir of the next
downstream sub-grid quadrant."
Justification for this approach would be helpful (add supporting references)

We assume this refers to lines 498-500 and not 498-490. This segment reads:

"Active DOC flows into a Labile DOC hydrological export pool, while the Slow and Passive DOC pools flow into a Refractory DOC hydrological pool (Fig. 2b)."

This formulation follows on from prior published developments made to the model code, but is unpacked more explicitly in the section by adding the following content:

"However, because the terrestrial Slow and Passive DOC pools (Camino-Serrano et al., 2018) are given the same residence time, these two pools are merged when exported (Lauerwald et al., 2017): Active DOC flows into a Labile DOC hydrological export pool, while the Slow and Passive DOC pools flow into a Refractory DOC hydrological pool (Fig. 2b), owing to the fact that the residence time of these latter soil DOC pools is the same in their original (ORCHIDEE-SOM) formulation (Camino-Serrano et al., 2018), and retained and merged into a single hydrological DOC pool in Lauerwald et al. (2017). The water residence times in each reservoir of each subgrid-scale quadrant determine the decomposition of DOC into CO2 within water reservoirs, before non-decomposed DOC is passed on to the next reservoir in the downstream subgrid quadrant."

In addition, to improve contextual understanding, in Section 2.3 (paragraph 1) we have added the following (in red) to this section:

"The non-respired half of the litter feeds into 'Active', 'Slow' and 'Passive' free DOC pools, which correspond to DOC reactivity classes in the soil column in an analogous extension to the standard CENTURY formulation (Parton et al., 1987)."

These water pool names are really confusing.

We combine your two above comments into an adaptation to the paragraph as follows. We believe the confusion arises from our description of the fast, slow and stream reservoirs with respect to headwaters. The paragraph has been adapted as follows:

"Note that while we do not explicitly simulate headwaters as they exist in a geographically determinant way in the real world, we do simulate what happens to the water before it flows into a water body large enough to be represented in the routing scheme by the water pool called 'stream', representing a real-world river upwards of roughly stream order 4. The 'fast' reservoir is thus the runoff water flow that is destined for entering the 'stream' water reservoir, and implicitly represents headwater streams by filling the spatial and temporal niche between overland runoff and the river stem."

seems like there would be less organic matter to leach from on higher slopes.

Yes, certainly an omission here. We have added in the line:

"In addition, places with higher elevation and slope in these regions tend to experience extreme cold, leading to lower NPP and so DOC leaching."
Equation 2: needs units, what does 12.011 represent? A carbon unit conversion?

This has now been altered to:

"Where the pCO\(_2\) (atm.) of a given (e.g. 'stream', 'fast', 'slow' and floodplain) water pool (pCO\(_2\)pool) is given by the dissolved CO\(_2\) concentration in that pool [C\(_{O2}\)(aq)], the molar weight of carbon (12.011 g mol\(^{-1}\)) and K\(_{CO2}\)."

Equation 3, 4, 6, ditto. If these are empirically derived parameters there needs to be a reference.

For Eq. 3 we add in the text: "Water temperature (\(T_{WATER}\), °C) isn’t simulated by the model, but is estimated here from the average daily surface temperature (\(T_{GROUND}\), °C) in the model (Eq. 3), a derivation calculated for ORCHILEAK by Lauerwald et al. (2017) and retained here."

For Eq. 4, the Schmidt number that is calculated is entirely from Wanninkhof, and cited therein in the following segment: "With our water temperature estimate, both K\(_{CO2}\) and the Schmidt number (Sc, Eq. 4) from Wanninkhof (1992) can be calculated, allowing for simulation of actual gas exchange velocities from standard conditions."

For Eq. 6, we follow the standard CENTURY soil carbon pool formulation (Parton et al., 1987) in which rates enter black boxes of soil carbon for each grid cell and are then re-divisible over desired quantities (area/volume etc), which is why for these we did not give units, as it is simply a discrete mass over discrete time.

More specifically, the CENTURY carbon pools, rate modifiers are determined based on soil organic dynamic in Parton et al. (1987) and then evaluated on other ecosystems (Eglin et al., 2010, Dimassi et al., 2018) for ORCHIDEE. A slightly modified version of this, with the same CENTURY parameters that now account for the priming effect, was derived by Guenet et al. (2016) and included in this version. The parameters in this equation are derived in the cited references (see Equations 1-8 in Guenet et al. 2016) and repeated in Guenet et al (2018). For clarity, we have made the following edit to the text, reflecting the fact that \(k\) is the standard decomposition rate in 1/time, the rate modifiers are zero-dimensional and SOC represents the mass of SOC, represented here by Kg as the SI unit of mass:

" Where IN\(_{SOC}\) is the carbon input to that pool, \(k\) is the SOC decomposition rate (1/dt), FOC (Kg) is a stock of matter interacting with this SOC pool to produce priming, \(c\) is a parameter controlling this interaction, SOC is the SOC reservoir (Kg), and \(\theta\), \(\Phi\) and \(\gamma\) the zero-dimensional moisture, temperature and soil texture rate modifiers that modulate decomposition in the code, and are originally determined by the CENTURY formulation (Parton et al., 1987) and subsequently re-estimated to include priming in Guenet et al. (2016, 2018)."

Figure 1. part k. K: assumption of soil C distribution, differences between continuous and discontinuous. Don’t know how well supported this is – perhaps some justification could be found in the literature.
Yes, this is only illustrative but can be found in the literature for example the top 1m of soil generally is richer in carbon in continuous over discontinuous regions, with the canonical snapshot of this captured by the NCSCD.

The caption has been edited to reflect this with the following: "(k) Turbation and soil carbon with depth (e.g. Hugelius et al., 2013; Tarnocai et al., 2009, (Koven et al., 2015))."

Terminology between headwaters, tributary in figure vs. manuscript text are confusing.

The terminology we agree is a bit confusing because of the nomenclature that is used in the model code and in preceding papers cited therein which refer to real-world water pools like streams as 'fast reservoir' and real-world water pools like rivers as 'stream reservoir'. However, as this figure is a cartoon, we feel it appropriate to use real-world terms for bodies such as streams and tributaries that are represented collectively in the model by both the 'fast' and 'stream' pool.

Thus in the caption text we include the following sentence: "Note that 'tributaries' in the Figure may be represented in the model by either the 'fast' or 'stream' pool, depending on their size."

Author Response to Interactive Comment by Anonymous Referee #2 on "ORCHIDEE MICT-LEAK(r5459), a global model for the production, transport and transformation of dissolved organic carbon from Arctic permafrost regions, Part 1: Rationale, model description and simulation protocol" by Simon P. K. Bowring et al.

Dear Anonymous Referee #2,

Thank you for taking the time to read and review our manuscript, and in doing so providing such diligent and constructive commentary for its improvement, which we hope we have been able to assimilate into its content to the greatest degree possible in our responses, which follow below.

Major Comments:

1. All abbreviations should be spelled out at their first usage in the Abstract as well as the main text. For instance, ORCHIDEE MICTLEAK should be spelled out in abstract as well as the main text, where this term is first mentioned. In addition, "IPSL", "DOC-C" and "MICT" are also not spelled out. Please check for all abbreviations throughout the manuscript and define them at the first usage.

1. We have included the full expansion of the acronyms identified by your review and included them in the main body of the text. In the abstract, we have included the full spelling of 'IPSL' (Institut Pierre Simon Laplace), to reflect the fact that this may not be a well-known institute, but have decided not to do the same for 'ORCHIDEE' in the abstract, as (1) this is a relatively well-known land surface model in the modelling
community, such that it may not be necessary to unpack its letters in an abstract; (ii) this unpacking is extremely lengthy, and may not be sufficiently informative to justify its inclusion to the text body of an abstract. Thus the unpacking occurs in line 72 of the text. Finally, we cannot spell out "ORCHIDEE MICT-LEAK" since the second half of the compound name (LEAK) is itself not an acronym, and refers to a version of the ORCHIDEE model called ORCHILEAK - hence our reduction of the new branch name presented in this manuscript from ORCHIDEE MICT-LEAK to ORCHIDEE M-L. The rationale for the ORCHILEAK name is now included in the text (L. 81-82) with the text "where the suffix 'LEAK' holds no acronym, and refers to the 'leakage' of carbon from terrestrial to aquatic realms)." Further, in the abstract we try to clarify the point that the presented model results from the merge of two separate code versions with the following text: "The model, ORCHIDEE MICT-LEAK, which represents the merger of previously described ORCHIDEE versions -MICT and -LEAK, mechanistically represents..."

2. Line 46: "... as the permafrost line migrates poleward over time." is incorrect, because there is no line in permafrost zone. However, there is boundary between continuous and discontinuous permafrost zones, and this boundary is slowly moving poleward over time. Please correct the phrase with respect to this suggestion.

3. Please edit English grammar throughout the manuscript more carefully. For example, in line 70 "To this end" is not clear. In addition, in line 62 "metabolising" should be "metabolizing".

4. Thank you for finding this grammatical inconsistency in our text, which reflects the inputs of authors using differing standards for English spelling. The GMD English language guidelines stipulate that "We accept all standard varieties of English in order to retain the author's voice. However, the variety should be consistent within each article". As such, we have chosen to homogenise the text for the UK variant. Thus 'metabolize' and its variants have now all been corrected to reflect this choice of English usage in the other text (e.g. lines 125-126), as have all other verbs that contain this ('-z') difference in spelling (e.g. 'mineralization' --> 'mineralisation', line 461) throughout the text. Further, "to this end" has been changed to "for this purpose".

Minor Comments:

1. Lines 50-51: "... the majority as dissolved organic carbon (DOC)." is not clear. Please cite some references supporting the statement. For instance, in the headwater of the Lena River basin, Suzuki et al. (2006) showed that DOC was a dominant form of riverine organic carbon transport because inorganic carbon and particulate organic carbon (POC) transport would be negligible on the basis of their observation data. Suzuki, K. et al. (2006), Nordic Hydrology, 37(3), 303-312, doi:10.2166/nh.2006.015.
Thank you for pointing out this unqualified statement. We have included the citation suggested in review.

This has been included in the text (now line 128).

3. Line 133-134: "... and DOC concentration are affected at watershed scale by parent material and ground ice condition (O’Donnell et al., 2016)." The statement is incomplete, because DOC concentration is also affected by active layer depth as the frozen ground table limits water infiltration into deeper soil layers, as shown by Suzuki et al. (2006).

Thank you for finding this error in conceptualisation. Indeed, we agree with the reviewer that this is a critical determinant of DOC concentrations, and have altered the text to reflect this with "DOC concentrations are affected at watershed scale by parent material, ground ice content (O’Donnell et al., 2016) and active layer depth (Suzuki et al., 2006)."

4. Line 169: "... and greater evapotranspiration (Zhang et al., 2009)." Please consider adding the study by Suzuki et al. (2018), wherein they have shown increasing evapotranspiration from the entire Arctic circumpolar Tundra due to summer warming. Suzuki, K. et al. (2018), Remote Sensing, 10(3), 402, doi:https://doi.org/10.3390/rs10030402.
Thank you for alerting us this additional citation that further strengthens the assertions made in this portion of the text (now line 187).

5. Line 373: "... non-conservative canopy DOC production rate of 9.2*10^-4 g DOC-C per gram ..." is not clear. Please rewrite more clearly.
Indeed, on reflection, this sentence is not particularly straightforward and has been adapted to make what has been calculated clearer to the reader. It now reads "From this we obtain a constant tree canopy DOC production rate of 9.2*10^-4 g DOC-C per gram of leaf biomass per day (Eq. 1). This is the same for all PFTs except those representing crops, for which this value equals 0, reflecting how at a very general level, crops are small and tend no to be characterised by high organic acid loss rates from leaves due to e.g. aphids, due to human control." (now lines 394-399).

6. Line 388: "3.5 Hydrological mobilisation of soil DOC" should be "3.5 Hydrological mobilization of soil DOC".
This has now been included (see Major Comments Response (3)).

7. Line 396: "... (see sections 'soil flooding' and 'floodplain representation')."
Please add the specific section numbers.
10

Here we realise that the section headings had changed since this part was written, and we had since merged the segments discussing floodplain representation. This is now reflected in the text body (line 424) which now reads: "(see section 2.8, 'Representation of floodplain hydrology and their DOC budget')."

8. Lines 520-522: Please consider citing Suzuki et al. (2006), because they observed very large DOC transport from a headwater basin of the Lena River basin.

Thank you for your suggestion. This has now been included.

9. Line 654: "... such as the photochemical breakdown of riverine OC...". Here, OC is not clear. Please define this and add explanation.

Thank you, this has been corrected to "dissolved organic carbon" (now line 691).

10. For equations (1)-(6): within the equations, variables are in italics but variables in the main text are in normal font. Please modify these for consistency.

Indeed, we had not noticed this inconsistency in the text, which has now been edited accordingly throughout.

12. In Figure 1, letters (a)-(m) are too small to read. Please enlarge the letters.

(note, no 11. in the original review document). The font size for the letter subheadings has been increased from 8 point to 12 point in Figure 1.

13. In the caption of Figure 1, line 1254, "(d) Hydrological mobilisation of soil DOC" should be "(d) Hydrological mobilization of soil DOC"

This remains as was (see choice of English in Major Comments (3)).

14. In the caption of Figure 2, line 1277 "Blue dashed boxes" should be "Blue colored boxes".

This change has been included in the document.
Title:

ORCHIDEE MICT-LEAK (r5459), a global model for the production, transport and transformation of dissolved organic carbon from Arctic permafrost regions, Part 1: Rationale, model description and simulation protocol.

Abstract

Few Earth System models adequately represent the unique permafrost soil biogeochemistry and its respective processes; this significantly contributes to uncertainty in estimating their responses, and that of the planet at large, to warming. Likewise, the riverine component of what is known as the 'boundless carbon cycle' is seldom recognised in Earth System modelling. Hydrological mobilisation of organic material from a ~1330–1580 PgC carbon stock to the river network results either in sedimentary settling or atmospheric 'evasion', processes widely expected to increase with amplified Arctic climate warming. Here, the production, transport and atmospheric release of dissolved organic carbon (DOC) from high-latitude permafrost soils into inland waters and the ocean is explicitly represented for the first time in the land surface component (ORCHIDEE) of a CMIP6 global climate model (Institut Pierre Simon Laplace (IPSL)). The model, ORCHIDEE MICT-LEAK, which represents the merger of previously described ORCHIDEE versions - MICT and - LEAK - mechanistically represents (a) vegetation and soil physical processes for high latitude snow, ice and soil phenomena, and (b) the cycling of DOC and CO2, including atmospheric evasion, along the terrestrial-aquatic continuum from soils through the river network to the coast, at 0.5° to 2° resolution. This paper, the first in a two-part study, presents the rationale for including these processes in a high latitude specific land surface model, then describes the model with a focus on novel process implementations, followed by a summary of the model configuration and simulation protocol. The results of these simulation runs, conducted for the Lena River basin, are evaluated against observational data in the second part of this study.

1 Introduction

High-latitude permafrost soils contain large stores of frozen, often ancient and relatively reactive carbon up to depths of over 30m. Soil warming caused by contemporary anthropogenic climate change can be expected to destabilise these stores (Schuur et al., 2015), via microbial or hydrological mobilisation following spring/summer thaw and riverine discharge (Vonk et al., 2015a) as the boundary between discontinuous and
Continuous permafrost migrates poleward and toward the continental interior over time. The high latitude soil carbon reservoir may amount to \(1300-1500\) PgC (Hugelius et al., 2013, 2014; Tarnocai et al., 2009) —over double that stored in the contemporary atmosphere, while the yearly lateral flux of carbon from soils to running waters may amount to about a fifth of net ecosystem carbon exchange (\(400\) TgC yr\(^{-1}\)), about \(40\%\) of which may be contributed by DOC (McGuire et al., 2009). Excluding the dissolved inorganic carbon component of this flux, as well as dissolved CO\(_2\) input from soils, the vast majority (\(85\%\)) of riverine organic carbon transfer to the Arctic Ocean occurs as dissolved organic carbon (DOC), as described in (e.g.) Suzuki et al. (2006).

The fact that, to our knowledge, no existing land surface models are able to adequately simultaneously represent this unique high latitude permafrost soil environment, the transformation of soil organic carbon (SOC) to its eroded particulate and DOC forms and their subsequent lateral transport, as well as the response of all these to warming, entails significant additional uncertainty in projecting global-scale biogeochemical responses to human-induced environmental change.

Fundamental to these efforts is the ability to predict the medium under which carbon transformation will occur: in the soil, streams, rivers or sea, and under what metabolising conditions —since these will determine the process mix that will ultimately enable either terrestrial redeposition and retention, ocean transfer, or atmospheric release of permafrost-derived organic carbon. In the permafrost context, this implies being able to accurately represent (i) the source, reactivity and transformation of released organic matter; and (ii) the dynamic response of hydrological processes to warming, since water phase determines carbon, heat, and soil moisture availability for metabolisation and lateral transport.

For this purpose, we take a specific version of the terrestrial component of the Institut Pierre Simon Laplace (IPSL) global Earth System model (ESM) ORCHIDEE (Organising Carbon and Hydrology In Dynamic Ecosystems), one that is specifically coded for, calibrated with and evaluated on high latitude phenomena and permafrost processes, called ORCHIDEE-MICT (where MICT stands for Me\(\)liorated Interactions between Carbon and Temperature (Guimberteau et al., 2018)). This code is then adapted to include DOC production in the soil (ORCHIDEE-SOM, Camino-Serrano et al., 2018), the "priming" of SOC (ORCHIDEE-PRIM, Guenet et al., 2016, 2018) and the riverine transport of DOC and CO\(_2\) including in-stream transformations, carbon and water exchanges with wetland soils and gaseous exchange between river surfaces and the atmosphere (ORCHILEAK, Lauerwald et al., 2017, where the suffix ‘LEAK’ holds no acronym, and refers to the ‘leakage’ of carbon from terrestrial to aquatic realms).

The resulting model, dubbed ORCHIDEE-MICT-LEAK, hereafter referred to as MICT-L for brevity, is therefore able to represent: (a) Permafrost soil and snow physics, thermodynamics to a depth of \(38\) m and dynamic soil hydrology to a depth of \(2\) m; (b) improved representation of biotic stress response to cold, heat and moisture in high latitudes; (c) Explicit representation of the active layer and frozen-soil hydrologic barriers; build-up of soil carbon stocks via primary production and vertical translocation (turbation) of SOC and DOC; (d) DOC leaching from tree canopies, atmospheric deposition, litter and soil organic matter, its adsorption/desorption to/from soil particles, its transport and transformation to dissolved CO\(_2\) (\(\text{CO}_2\)\(_\text{aq}\)) and atmospheric...
release, as well as the production and hydrological transport of plant root-zone derived dissolved CO₂ (e) Improved representation of C cycling on floodplains; (f) Priming of organic matter in the soil column and subsequent decomposition dynamics. In combination, these model properties allow us to explore the possibility of reproducing important emergent phenomena observed in recent empirical studies (Fig. 1) arising from the interaction of a broad combination of different processes and factors.

To our knowledge very few attempts have been made at the global scale of modelling DOC production and lateral transfer from the permafrost region that explicitly accounts for such a broad range of high latitude-specific processes, which in turn allows us to match and evaluate simulation outputs with specific observed processes, enhancing our ability to interpret the output from these models and improve our understanding of the processes represented. The only other attempt at doing so is a Pan-Arctic modelling study by Kicklighter et al. (2013), which is based on a relatively simplified scheme for soil, water and biology. The following segment briefly overviews the dynamics, emergent properties and their overall significance across scales, of permafrost region river basins.

A giant, reactive, fast-draining funnel: A permafrost basin overview

Permafrost has a profound impact on Arctic river hydrology. In permafrost regions, a permanently frozen soil layer acts as a ‘cap’ on ground water flow (see ‘permafrost barrier’, right hand side of Fig. 1). This implies that: (i) Near-surface runoff becomes by far the dominant flowpath draining permafrost watersheds (Ye et al., 2009), as shown in Fig. 1d; (ii) The seasonal amplitude of river discharge, expressed by the ratio of maximum to minimum discharge (Qmax/min in Fig. 1), over continuous versus discontinuous permafrost catchments is higher as a result of the permafrost barrier; (iii) This concentration of water volume near the surface causes intense leaching of DOC from litter and relevant unfrozen soil layers (Fig. 1g, 1d, e.g. Suzuki et al., 2006 Drake et al., 2015; Spencer et al., 2015; Vonk et al., 2015ab); (iv) Permafrost SOC stocks beneath the active layer are physically and thermally shielded from aquatic mobilization and metabolism, respectively (Fig. 1g).

Rapid melting of snow and soil or river ice during spring freshet (May-June) drives intensely seasonal discharge, with peaks often two orders of magnitude (e.g. Van Vliet et al., 2012) above baseflow rates (Fig. 1d). These events are the cause of four, largely synchronous processes: (i) Biogenic matter is rapidly transported from elevated headwater catchments (Fig. 1, right hand side) (McClelland et al., 2016); (ii) Plant material at the soil surface is intensely leached, with subsequent mobilization and transformation of this dissolved matter via inland waters (Fig. 1d,b,j); During spring freshet, riverine DOC concentrations increase and bulk annual marine DOC exports are dominated by the terrestrial DOC flux to the rivers that occurs at this time (Holmes et al., 2012). Indeed, DOC concentrations during the thawing season tend to be greater than or equal to those in the Amazon particularly in the flatter Eurasian rivers (Holmes et al., 2012; McClelland et al., 2012), and DOC concentrations are affected at watershed scale by parent material, ground ice content (O’Donnell et al., 2016) and active layer depth (Suzuki et al., 2006).
(iii) Sudden inundation of the floodplain regions in spring and early summer (Fig. 1h), further spurs lateral flow of both particulate and dissolved matter in the process and its re-deposition (Zubrycki et al., 2013), or atmospheric evasion (Fig. 1j,m); (iv) Snowmelt-induced soil water saturation, favoring the growth of moss and sedge-based ecosystems (e.g. Selvam et al., 2017; Tarnocai et al., 2009; Yu, 2011) and the retention of their organic matter (OM), i.e., peat formation, not shown in Fig. 1 as this isn’t represented in this model version, but is generated in a separate branch of ORCHIDEE (Qi et al., 2018).

Mid-summer river low flow and a deeper active layer allow for the hydrological intrusion and leaching of older soil horizons (e.g. the top part of Pleistocene-era Yedoma soils), and their subsequent dissolved transport (e.g. Wickland et al., 2018). These sometimes-ancient low molecular weight carbon compounds appear to be preferentially and rapidly metabolized by microbes in headwater streams (Fig. 1j), which may constitute a significant fraction of aggregate summer CO$_2$ evasion in Arctic rivers (Denfeld et al., 2013; Vonk et al., 2015), This is likely due to the existence of a significant labile component of frozen carbon (Drake et al., 2015; Vonk et al., 2013; Woods et al., 2011).

CO$_2$ evasion rates from Arctic inland waters (Fig. 1e,m), which include both lakes and rivers, are estimated to be 40-84 Tg C yr$^{-1}$ (McGuire et al., 2009), of which 15-30 Tg C yr$^{-1}$ or one-third of the total inland evasion flux, is thought to come from rivers. Recent geostatistically determined estimates of boreal lake annual emissions alone now stands at 74-347 Tg C yr$^{-1}$ (Hastie et al., 2018), although this is likely a substantial overestimate (Bogard et al., 2019), which potentially lowers the riverine fraction of total CO$_2$ evasion. These numbers should be compared with estimates of Pan-Arctic DOC discharge from rivers of 25-36 Tg C yr$^{-1}$ (Holmes et al., 2012; Raymond et al., 2007). The subsequent influx of terrestial carbon to the shelf zone is thought to total 45-54 Tg C yr$^{-1}$, Rivers supply the Arctic Ocean an estimated 34 Tg of carbon-equivalent DOC (DOC-C) yr$^{-1}$ (Holmes et al., 2012), while depositing 5.8 Tg C yr$^{-1}$ of particulate carbon, these being sourced from those rivers draining low and high elevation headwaters, respectively (McClelland et al., 2016). These dynamics are all subject to considerable amplification by changes in temperature and hydrology (e.g. Drake et al., 2015; Frey and McClelland, 2009; Tank et al., 2018).

Average annual discharge in the Eurasian Arctic rivers has increased by at least 7% between 1936-1999 (Peterson et al., 2002), driven by increasing temperatures and runoff (Bereozvskaya et al., 2005), and the subsequent interplay of increasing annual precipitation, decreasing snow depth and snow water equivalent (SWE) mass (Kunkel et al., 2016; Mudryk et al., 2015), and greater evapotranspiration (Suzuki et al., 2018; Zhang et al., 2009). Although net discharge trend rates over N. America were negative over the period 1964-2003, since 2003 they have been positive on average (Dery et al., 2016). These dynamic and largely increasing hydrologic flux trends point towards temperature and precipitation - driven changes in the soil column, in which increased soil water/snow thaw and microbial activity (Graham et al., 2012; MacKelpang et al., 2011; Schuur et al., 2009) converge to raise soil leaching and DOC export rates to the river basin and beyond (e.g. Vonk et al., 2015b). Further, microbial activity generates its own heat, which incubation experiments have shown may be sufficient to significantly warm the soil further (Hollesen et al., 2015), in a positive feedback.
Arctic region fire events are also on the rise and likely to increase with temperature and severity over time (Ponomarev et al., 2016). The initial burning of biomass is accompanied by active layer deepening, priming of deeper soil horizons (De Baets et al., 2016), and a significant loading of pyrogenic DOC in Arctic watersheds, up to half of which is rapidly metabolized (Myers-Pigg et al., 2015).

In these contexts, the implications of (polar-amplified) warmer temperatures leading to active layer deepening towards the future (transition from Continuous to Discontinuous Permafrost, as shown in the upper/lower segments of Fig. 1) are clear and unique: potentially sizeable aquatic mobilization and microbial metabolism (Xue, 2017) of dissolved and eroded OM, deeper hydrological flow paths, an increase in total carbon and water mass and heat transfer to the aquatic network and, ultimately, the Arctic Ocean and atmosphere (Fig. 1).

The advantage of having a terrestrial model that can be coupled to a marine component of an overarching global climate model (GCM) is in this case the representation of a consistent transboundary scheme, such that output from one model is integrated as input to another. This is particularly important given the context in which these terrestrial outflows occur:

Because of its small size, a uniquely large and shallow continental shelf, the global climatological significance of its seasonal sea ice (Rhein et al., 2013) and its rapid decline (Findlay et al., 2015), the Arctic Ocean has been described as a giant estuary (McClelland et al., 2012), acting as a funnel for the transport, processing and sedimentation of terrestrial OM. Because of its small surface area and shallow seas (Jakobsson, 2002), the Arctic Ocean holds relatively little volume and is consequently sensitive to inputs of freshwater, heat, alkalinity and nutrients that flush out from terrestrial sources, particularly at discharge peak.

High suspended particle loads in river water as they approach the mouth (Heim et al., 2014) cause lower light availability and water albedo and hence higher temperatures (Bauch et al., 2013; Janout et al., 2016), which can affect the near-shore sea ice extent, particularly in spring (Steele and Ermold, 2015). Volumes of riverine freshwater and total energy flux (Lammers et al., 2007) are expected to increase with warmer temperatures, along with an earlier discharge peak (Van Vliet et al., 2012, 2013). In doing so, freshwaters may in the future trigger earlier onset of ice retreat (Stroeve et al., 2014; Whitefield et al., 2015) via a freshwater albedo, ice melt, seawater albedo, ice melt, feedback, amplified by intermediary state variables such as water vapour and cloudiness (Serreze and Barry, 2011).

Both terrestrially-exported and older shelf carbon in the Arctic Ocean face considerable disruption (McGuire et al., 2009; Schuur et al., 2015) from the combined effects of increased freshwater, heat, sediment, nutrient and organic carbon flows from rapidly warming Arctic river watersheds, as well as those from melting sea ice, warmer marine water temperatures and geothermal heat sources (Janout et al., 2016; Shakhova et al., 2015). Because ORCHIDEE is a sub-component of the overarching IPSL ESM, there is scope for coupling riverine outputs of water, DOC, CO$_2$(aq) and heat from the terrestrial model as input for the IPSL marine components (Fig. 1). Nonetheless, these are not the...
objectives of the present paper, whose aim is rather to validate the simulated variable
output produced by the model described in detail below against observations and
empirical knowledge for the Lena basin, but are included here descriptively to scope the
plausible future applications of ORCHIDEE MICT-LEAK, given our present empirical
understanding of their potential significance. The choice of the Lena River basin in
Eastern Siberia as the watershed of study for model evaluation owes itself to its size, the
presence of floodplains and mountain areas which allow us to test the model behavior
for contrasting topography, the relatively low impact of damming on the river, given that
ORCHIDEE only simulates undammed fluvial 'natural flow', and its mixture of
continuous and discontinuous permafrost with tundra grassland in the north and boreal
forests in the south, and is described in greater detail in Part 2 of this study.

The Methods section summarises the model structure and associated rationale for each of
the model sub-branches or routines relevant to this study, and follows with the setup
and rationale for the simulations carried out as validation exercises.

2 Methods

This section overviews the processes represented in the model being described in this
manuscript, which is referred to as ORCHIDEE MICT-LEAK, hereafter referred to MICT-L
for brevity. MICT-L is at its heart a merge of two distinct models: the high-latitude land
surface component of the IPSL Earth System Model ORCHIDEE MICT, and the DOC-
production and transport branch of ORCHIDEE's default or 'trunk' version (Krinner et
al., 2005), ORCHILEAK. The original merge of these two code sets was between
ORCHILEAK and ORCHIDEE-MICT, which are described in Camino-Serrano et al.
(2018)/Lauerwald et al. (2017) and Guimberteau et al. (2018), respectively.

However, numerous improvements in code performance and process additions post-
dating these publications have been included in this code. Furthermore, novel processes
included in neither of these two core models are added to MICT-L, such as the diffusion
of DOC through the soil column to represent its turbation and preferential stabilisation
at depth in the soil, as described in Section 2.11. 

In terms of code architecture, the resulting model is substantially different from either
of its parents, owing to the fact that the two models were developed on the basis of
ORCHIDEE trunk revisions 2728 and 3976 for ORCHILEAK and MICT respectively, which
have a temporal model development distance of over 2 years, and subsequently evolved
in their own directions. These foundational differences, which mostly affect the
formulation of soil, carbon and hydrology schemes, mean that different aspects of each
are necessarily forced into the subsequent code. Where these differences were
considered scientific or code improvements, they were included in the resulting scheme.
Despite architectural novelties introduced, MICT-L carries with it a marriage of much
the same schemes detailed exhaustively in Guimberteau et al. (2018) and Lauerwald et
al. (2017). As such, the following model description details only new elements of the
model, those that are critical to the production and transport of DOC from permafrost
regions, and parameterisations specific to this study (Fig. 2).
MICT-L is based largely on ORCHIDEE-MICT, into which the DOC production, transport and transformation processes developed in the ORCHILEAK model version and tested insofar only for the Amazon, have been transplanted, allowing for these same processes to be generated in high latitude regions with permafrost soils and a river flow regime dominated by snow melt. The description that ensues roughly follows the order of the carbon and water flow chain depicted in Fig. 2b. At the heart of the scheme is the vegetative production of carbon, which occurs along a spectrum of 13 plant functional types (PFTs) that differ from one another in terms of plant physiological and phenological uptake and release parameters (Krinner et al., 2005). Together, these determine grid-scale net primary production. In the northern high latitudes, the boreal trees (PFTs 7-9) and C3 grasses (PFT 10) dominate landscape biomass and primary production. Thus, in descending order yearly primary production over the Lena basin is roughly broken down between C3 grasses (48%), boreal needleleaf summergreen trees (27%), boreal needleleaf evergreen trees (12%), boreal broadleaf summergreen trees (8%) and temperate broad-leaved evergreen trees (6%). Naturally these basin aggregates are heterogeneous distributed along latitude and temperature contours, with grasses/tundra dominating at the high latitudes and (e.g.) temperate broadleaf trees existing only at the southern edges of the basin.

2.2 Biomass generation (Fig. 1a)

Biomass generation, consisting of foliage, roots, above and below –ground sap and heart wood, carbon reserves and fruit pools in the model, results in the transfer of these carbon stores to two downstream litter pools, the structural and metabolic litter (Figure 2b). This distinction, defined by lignin concentration of each biomass pool (Krinner et al., 2005), separates the relatively reactive litter fraction such as leafy matter from its less-reactive, recalcitrant counterpart (woody, ‘structural’ material), with the consequence that the turnover time of the latter is roughly four-fold that of the former. These two litter pools are further discretised into above and below –ground pools, with the latter explicitly discretised over the first two metres of the soil column, a feature first introduced to the ORCHIDEE model by Camino-Serrano et al. (2014, 2018). This marks a significant departure from the original litter formulation in ORCHIDEE-MICT, in which the vertical distribution of litter influx to the soil carbon pool follows a prescribed root profile for each PFT. This change now allows for the production of DOC from litter explicitly at a given soil depth in permafrost soils.

2.3 DOC generation and leaching (Fig. 1b)

The vast majority of DOC produced by the model is generated initially from the litter pools via decomposition, such that half of all of the decomposed litter is returned to the atmosphere as CO₂, as defined by the microbial carbon use efficiency (CUE) – the fraction of carbon assimilated versus respired by microbes post-consumption – here set at 0.5 following Manzoni et al. (2012). The non-respired half of the litter feeds into ‘Active’, ‘Slow’ and ‘Passive’ free DOC pools, which correspond to DOC reactivity classes in the soil column in an analogous extension to the standard CENTURY formulation (Parton et al., 1987). Metabolic litter contributes exclusively to the Active DOC pool, while structural litter feeds into the other two, the distribution between them dependent on the lignin content of the Structural litter. The reactive SOC pools then derive directly from this DOC reservoir, in that fractions of each DOC pool, defined again by the CUE, are
directly transferred to three different SOC pools, while the remainder adds to the heterotrophic soil respiration. Depending on clay content and bulk density of the soil, a fraction of DOC is adsorbed to the mineral soil and does not take part in these reactions until it is gradually desorbed when concentrations of free DOC decrease in the soil column. This scheme is explained in detail in Camino-Serrano (2018). The value of the fractional redistributions between free DOC and SOC after adsorption are shown in Fig. 2b.

The approximate ratio of relative residence times for the three SOC pools in our model (Active : Slow : Passive) is (1 : 37 : 1618) at a soil temperature of 5°C, or 0.843 years, 31 yrs. and 1364 yrs. for the three pools respectively (Fig. 2b). These are based on our own exploratory model runs and subsequent calculations. The residence times of the active DOC pool is ~7 days (0.02 yrs.), while the slow and passive DOC pools both have a residence time of ~343 days (0.94 yrs.) at that same temperature. Upon microbial degradation in the model, SOC of each pool reverts either to DOC or to CO₂, the ratio between these determined again by the CUE which is set in this study at 0.5 for all donor pools, in keeping with the parameter configuration in Lauerwald et al., (2017) from Manzoni et al. (2012). This step in the chain of flows effectively represents leaching of SOC to TOC. Note that the reversion of SOC to DOC occurs only along Active-Active, Slow-Slow and Passive-Passive lines in Fig. 2b, while the conversion of DOC to SOC is distributed differently so as to build up a reasonable distribution of soil carbon stock reactivities. Note also that the microbial CUE is invoked twice in the chain of breakdown, meaning that the ‘effective’ CUE of the SOC-litter system is approximately 0.25.

2.4 Throughfall and its DOC (Fig. 1c)

In MICT-L, DOC generation also occurs in the form of wet and dry atmospheric deposition and canopy exudation, collectively attributed to the throughfall, i.e. the amount of precipitation reaching the ground. Wet atmospheric deposition originates from organic compounds dispersed in atmospheric moisture which become deposited within rainfall, and are assumed here to maintain a constant concentration. This concentration we take from the average of reported rainfall DOC concentrations in the empirical literature measured at sites >55°N [Bergkvist and Folkeson, 1992; Clarke et al., 2007; Fröberg et al., 2006; Lindroos et al., 2011; Rosenqvist et al., 2010; Starr et al., 2003; Wu et al., 2010], whose value is 3 mg C L⁻¹ of rainfall. Dry DOC deposition occurs through aerosol-bound organic compounds, here assumed to fall on the canopy; canopy exudation refers to plant sugars exuded from the leaf surface (e.g. honey dew) or from their extraction by heterotrophs such as aphids. These two are lumped together in our estimates of canopy DOC generation (gDOC per g leaf carbon), which is calibrated as follows.

We take the average total observation-based throughfall DOC flux rate per m² of forest from the aforementioned literature bundle (15.7 g C m⁻² yr⁻¹) and subtract from it the wet deposition component (product of rainfall over our simulation area and the rain DOC content). The remainder is then the canopy DOC, which we scale to the average leaf biomass simulated in a 107-year calibration run over the Lena river basin. From this we obtain a constant, i.e. mean canopy DOC production rate of $9.2 \times 10^4$ g DOC-C per gram of leaf biomass per day (Eq. 1). This is the same for all PFTs except those representing crops.
for which this value equals 0, reflecting how at a very general level, crops are small and tend no to be characterised by high organic acid loss rates from leaves due to e.g. aphids, due to human control. Note that this production of DOC should be C initially fixed by photosynthesis, but it is here represented as an additional carbon flux. The dry deposition of DOC through the canopy is given by:

\[ TF_{\text{DRY}} = M_{\text{LEAF}} \times 9.2 \times 10^{-4} \frac{dt}{\text{day}} \]

Where \( TF_{\text{DRY}} \) is dry deposition of DOC from the canopy, \( M_{\text{LEAF}} \) is leaf biomass, \( dt \) is the timestep of the surface hydrology and energy balance module (30min) and day is 24 hours. This accumulates in the canopy and can be flushed out with the throughfall and percolates into the soil surface or adds to the DOC stock of surface waters. The wet and canopy deposition which hits the soil is then assumed to be split evenly between the labile and refractory DOC pools (following Aitkenhead-Peterson et al., 2003).

2.5 Hydrological mobilisation of soil DOC (Fig. 1d)

All DOC pools, leached from the decomposition of either litter and SOC or being throughfall inputs, reside at this point in discrete layers within the soil column, but are now also available for vertical advection and diffusion, as well as lateral export from the soil column as a carbon tracer, via soil drainage and runoff.

Export of DOC from the soil to rivers occurs through surface runoff, soil-bottom drainage, or flooding events (see section 2.8, ‘Representation of floodplain hydrology and their DOC budget’). Runoff is activated when the maximum water infiltration rate of the specific soil has been exceeded, meaning that water arrives at the soil surface faster than it can enter, forcing it to be transported laterally across the surface. DOC is drawn up into this runoff water flux from the first 5 layers of the soil column, which correspond to a cumulative source depth of 4.5cm.

Drainage of DOC occurs first as its advection between the discrete soil layers, and its subsequent export from the 11th layer, which represents the bottom of the first 2m of the soil column, from which export is calculated as a proportion of the DOC concentration at this layer. Below this, soil moisture and DOC concentrations are no longer explicitly calculated, except in the case that they are cryoturbated below this, up to a depth of 3m. DOC drainage is proportional to but not a constant multiplier of the water drainage rate for two reasons. First, as it water percolates through the soil column, it carries DOC along from one layer to another through the entirety of the soil column, but this percolation is blocked when the soil is entirely frozen, i.e. it is assumed that all soil pores are filled with ice which blocks percolation. This implies that DOC transport is not just determined by what enters from the top but also by the below ground production from litter, the sorption and desorption to and from particulate soil organic carbon in the soil column, its decomposition within the soil column, and water vertical transport entraining DOC between the non-frozen soil layers using the hydraulic conductivity calculated by the model as a function of soil texture, soil carbon and time-dependent soil moisture (Guimberteau et al., 2018).
Secondly, in order to account for preferential flow paths in the soil created by the subsoil actions of flora and fauna, and for the existence of non-homogenous soil textures at depth that act as aquitards, DOC infiltration must account for the fact that area-aggregated soils drain more slowly, increasing the residence time of DOC in the soil. Thus a reduction factor which reduces the vertical advection of DOC in soil solution by 80% compared to the advection is applied to represent a slow down in DOC percolation through the soil and increase its residence time there.

In MICT-L, as in ORCHILEAK, a 'poor soils' module reads off from a map giving fractional coverage of land underlain by Podzols and Arenosols at the 0.5° grid-scale, as derived from the Harmonized World Soil Database [Nachtergaele, 2010]. Due to their low pH and nutrient levels, areas identified by this soil-type criterion experience soil organic matter decomposition rates half that of other soils [Lauerwald et al. (2017), derived from Bardy et al. (2011); Vitousek & Sanford (1986); Vitousek & Hobbie (2000)]. To account for the very low DOC-filtering capacity of these coarse-grained, base- and clay-poor soils (DeLuca & Boisvenue 2012, Fig. 2b), no reduction factor in DOC advection rate relative to that of water in the soil column is applied when DOC is generated within these 'poor soils'.

By regulating both decomposition and soil moisture flux, the "poor soil" criterion effectively serves a similar if not equal function to a soil 'tile' for DOC infiltration in the soil column (inset box of Fig. 1), because soil tiles (forest, grassland/tundra/cropland and bare soil) are determinants of soil hydrology which affects moisture-limited decomposition. Here however, the 'poor soil' criterion is applied uniformly across the three soil tiles of each grid cell. This modulation in MICT-L is of significance for the Arctic region, given that large fractions of the discontinuous permafrost region are underlain by Podzols, particularly in Eurasia. For the Arctic as a whole, Podzols cover ~15% of total surface area [DeLuca and Boisvenue, 2012]. Further, in modelled frozen soils, a sharp decline in hydraulic conductivity is imposed by the physical barrier of ice filling the soil pores, which retards the flow of water to depth in the soil, imposing a cap on drainage and thus potentially increasing runoff of water laterally, across the soil surface [Gouttevin et al., 2012]. In doing so, frozen soil layers overlain by liquid soil moisture will experience enhanced residence times of water in the carbon-rich upper soil layers, potentially enriching their DOC load. Note that ice wedges, an important component of permafrost landscapes and their thaw processes, are not included in the current terrestrial representation, but have been previously simulated in other models [Lee et al., 2014].

Thus, for all the soil layers in the first 2m, DOC stocks are controlled by production from litter and SOC decay, their advection, diffusion, and consumption by DOC mineralization, as well as buffering by adsorption and desorption processes.

### 2.6 Routing Scheme:

The routing scheme in ORCHIDEE, first described in detail in Ngo-Duc et al. (2007) and presented after some version iterations in Guimberteau et al. (2012), is the module which when activated, represents the transport of water collected by the runoff and drainage simulated by the model along the prescribed river network in a given watershed. In doing so, its purpose is to coarsely represent the hydrologic coupling...
between precipitation inputs to the model and subsequent terrestrial runoff and drainage (or evaporation) calculated by it on the one hand, and the eventual discharge of freshwater to the marine domain, on the other. In other words, the routing scheme simulates the transport of water by rivers and streams, by connecting rainfall and continental river discharge with the land surface.

To do so, the routing scheme first inputs a map of global watersheds at the 0.5 degree scale [Oki et al., 1999; Vorosmarty et al., 2000] which gives watershed and sub-basin boundaries and the direction of water-flow based on topography to the model. The water flows themselves are comprised of three distinct linear reservoirs within each sub-basin (‘slow’, ‘fast’, ‘stream’). Each water reservoir is represented at the scale (here: 4 sub-grid units per grid cell), and updated with the lateral in- and outflows at a daily time-step. The ‘slow’ water reservoir aggregates the soil drainage, i.e. the vertical runoff from the 11th layer (2 m depth) of the soil column, effectively representing ‘shallow groundwater’ transport and storage. The ‘fast’ water reservoir aggregates surface runoff simulated in the model, effectively representing overland hydrologic flow. The ‘fast’ water reservoir aggregates surface runoff simulated in the model, effectively representing overland hydrologic flow. The ‘slow’ and ‘fast’ water reservoirs feed a delayed outflow to the ‘stream’ reservoir of the next downstream sub-grid quadrant.

The water residence time in each reservoir depends on the nature of the reservoir (increasing residence time in the order: stream < fast < slow reservoir). More generally, residence time locally decreases with topographic slope and the grid-cell length, used as a proxy for the main tributary length [Ducharne et al., 2003; Guimberteau et al., 2012]. This is done to reproduce the hydrological effects of geomorphological and topographic factors in Manning’s equation [Manning, 1891] and determines the time that water and DOC remain in soils prior to entering the river network or groundwater. In this way the runoff and drainage are exported from sub-unit to sub-unit and from grid-cell to grid-cell.

2.7 Grid-scale water and carbon routing (Fig 1f, 1g)

Water-borne, terrestrially-derived DOC and dissolved CO₂ in the soil solution are exported over the land surface using the same routing scheme. When exported from soil or litter, DOC remains differentiated in the numerical simulations according to its initial reactivity within the soil (Active, Slow, Passive). However, because the terrestrial Slow and Passive DOC pools (Camino-Serrano et al., 2018) are given the same residence time, these two pools are merged when exported [Lauerwald et al., 2017]. Active DOC flows into a Labile DOC hydrological export pool, while the Slow and Passive DOC pools flow into a Refractory DOC hydrological pool (Fig 2b), owing to the fact that the residence time of these latter soil DOC pools is the same in their original (ORCHIDEE-SOM) formulation [Camino-Serrano et al., 2018], and retained and merged into a single hydrological DOC pool in Lauerwald et al., 2017. The water residence times in each reservoir of each sub-grid scale quadrant determine the decomposition of DOC into CO₂ within water reservoirs, before non-decomposed DOC is passed on to the next reservoir in the downstream sub-grid quadrant.
The river routing calculations, which occur at a daily timestep, are then aggregated to one-day for the lateral transfer of water, CO$_2$(aq) and DOC from upstream grid to downstream grid according to the river network. Note that carbonate chemistry in rivers and total alkalinity routing are not calculated here.

In this framework, the 'fast' and 'slow' residence times of the water pools in the routing scheme determine the time that water and DOC remains in overland and groundwater flow before entering the river network. Note that while we do not explicitly simulate headwaters, as they exist in a geographically determinant way in the real world, we do simulate what happens to the water before it flows into a water body large enough to be represented in the routing scheme by the water pool called 'stream', representing a real-world river of stream order 4 or higher. The 'fast' reservoir is thus the runoff water flow, that is destined for entering the 'stream' water reservoir, and implicitly represents headwater streams of Strahler order 1 to 3 by filling the spatial and temporal niche between overland runoff and the river stem. The dynamics of headwater hydrological and DOC dynamics (Section 2.10) are of potentially great significance with respect to carbon processing, as headwater catchments have been shown to be 'hotspots' of carbon metabolism and outgassing in Arctic rivers, despite their relatively small areal fraction (Denfeld et al., 2013; Drake et al., 2015; Mann et al., 2015; Suzuki et al., 2006; Venkiteswaran et al., 2014; Vonk et al., 2013, 2015a, 2015b). Thus, in what follows in this study, we refer to what in the code are called the 'fast' and 'stream' pools, which represent the small streams and large stream or river pools, respectively, using 'stream' and 'river' to denote these from hereon in.

Furthermore, the differentiated representation of water pools as well as mean grid cell slope, combined with the dynamic active layer simulated for continuous versus discontinuous permafrost, is important for reproducing the phenomena observed by Kutscher et al. (2017) and Zhang et al. (2017) for sloping land as shown on the right hand side of Fig. 1. In discontinuous permafrost and permafrost free regions, these phenomena encompass landscape processes (sub-grid in the model), through which water flow is able to re-infiltrate the soil column and so leach more refractory DOC deeper in the soil column, leading to a more refractory signal in the drainage waters. In contrast, in continuous permafrost region, the shallow active layer will inhibit the downward re-infiltration flux of water and encourage leaching at the more organic-rich and labile surface soil layer, resulting in a more labile DOC signal from the drainage in these areas (Fig. 1). In addition, places with higher elevation and slope in these regions tend to experience extreme cold, leading to lower NPP and so DOC leaching. The re-infiltration processes mentioned are thought to be accentuated in areas with higher topographic relief (Jasechko et al., 2016), which is why they are represented on sloping areas in Fig. 1.

2.8 Representation of floodplain hydrology and their DOC budget (Fig. 1e,1h)

The third terrestrial DOC export pathway in MICT-L is through flooding of floodplains, a transient period that occurs when stream water is forced by high discharge rates over the river 'banks' and flows onto a flat floodplain area of the grid cell that the river crosses, thus inundating the soil. Such a floodplain area is represented as a fraction of a grid-cell with the maximum extent of inundation, termed the 'potential flooded area' being predefined from a forcing file (Tootchi et al., 2019). Here, the DOC pools that are
already being produced in these inundated areas from litter and SOC decomposition in the first 5 layers of the soil column are directly absorbed by the overlying flood waters. These flood waters may then either process the DOC directly, via oxidation to CO₂ (Sections 2.10, 2.11) or return them to the river network, as floodwaters recede to the river main stem, at which point they join the runoff and drainage export flows from upstream.

MICT-L includes the floodplain hydrology part of the routing scheme (D’Orgeval et al., 2008; Guimberteau et al., 2012), as well as additions and improvements described in Lauerwald et al. (2017). The spatial areas that are available for potential flooding are pre-defined by an input map originally based on the map of Prigent et al. (2007). However, for this study, we used an alternative map of the “regularly flooded areas” derived from the method described in Tootchi et al. (2019), which in this study uses an improved input potential flooding area forcing file specific to the Lena basin, that combines three high-resolution surface water and inundation datasets derived from satellite imagery: GEEMS-D15 (Fluet-Chouinard et al., 2015), which results from the downscaling of the map of Prigent et al. (2007) at 15-arc-sec (ca 500 m at Equator); ESA-CCI land cover (at 300 m ~ 10 arc-sec); and JRC surface water at 1 arc-sec (Pekel et al., 2016). The ‘fusion’ approach followed by this forcing dataset stems from the assumption that the potential flooding areas identified by the different datasets are all valid despite their uncertainties, although none of them is exhaustive. The resulting map was constructed globally at the 15 arc-sec resolution and care was taken to exclude large permanent lakes from the potential flooding area based on the HydroLAKES database (Messager et al., 2016). In the Lena river basin, the basin against which we evaluate ORCHIDEE MICT-LEAK in Part 2 of this study, this new potential floodplains file gives a maximum floodable area of 12.1% (2.4×10⁶ km²) of the 2.5×10⁶ km² basin, substantially higher than previous estimates of 4.2% by Prigent et al. (2007),

With this improved forcing, river discharge becomes available to flood a specific pre-defined floodplain grid fraction, creating a temporary floodplains hydrologic reservoir, whose magnitude is defined by the excess of discharge at that point over a threshold value, given by the median simulated water storage of water in each grid cell over a 30 year period. The maximum extent of within-grid flooding is given by another threshold, the calculated height of flood waters beyond which it is assumed that the entire grid is inundated. This height, which used to be fixed at 2 m, is now determined by the 90th percentile of all flood water height levels calculated per grid cell from total water storage of that grid cell over a reference simulation period for the Lena basin, using the same methodology introduced by Lauerwald et al. (2017). The residence time of water on the floodplains $\tau_{\text{flood}}$ is a determinant of its resulting DOC concentration, since during this period it appropriates all DOC produced by the top 5 layers of the soil column.

2.9 Oceanic outflow (Fig 1i)

Routing of water and DOC through the river network ultimately lead to their export from the terrestrial system at the river mouth (Fig. 1), which for high latitude rivers are almost entirely sub-deltas of the ‘greater estuary’, described by McCllland et al. (2012), draining into the Arctic Ocean. Otherwise, the only other loss pathway for carbon export once in the river network is through its decomposition to CO₂ and subsequent
2.10 Dissolved CO₂ export and river evasion (Fig. 1)

Dissolved CO₂ (CO₂(aq)) exports are simulated by first assuming a constant concentration of CO₂(aq) with a surface runoff and drainage water fluxes of 20 and 2 mg C l⁻¹, corresponding to a pCO₂ of 50,000 μ atm and 5000 μ atm at 25°C in the soil column, respectively. These quantities are then scaled with total (root, microbial, litter) soil respiration by a scaling factor first employed in Lauerwald et al. (2019, in review). In the high latitudes soil respiration is dominantly controlled by microbial decomposition, and for the Lena basin initial model tests suggest that its proportional contribution to total respiration is roughly 90%, versus 10% from root respiration. Thus CO₂(aq) enters and circulates the rivers via the same routing scheme as that for DOC and river water. The lateral transfers with the atmosphere, which is a function of its solubility (Kₐ) with respect to the temperature of the water surface (Tₐ)

\[
pCO₂_{pool} = \frac{[CO₂(aq)]}{12.011 + K_{CO₂}}
\]

Where the pCO₂ (atm.) of a given (e.g. ‘stream’, ‘fast’, ‘slow’ and floodplain) water pool (pCO₂(pool)) is given by the dissolved CO₂ concentration in that pool [CO₂(aq)], the molar weight of carbon (12.011 g mol⁻¹) and Kₐ. Water temperature (T_w (°C)) isn’t simulated by the model, but is derived here from the average daily surface temperature (T_avg (°C)) in the model (Eq. 3), a derivation calculated for ORCHIDEE by Lauerwald et al. (2017) and retained here. Note that while dissolved CO₂ enters the terrestrial reservoir from organic matter decomposition, it is also generated in situ within the river network as DOC is respired microbially.

With our water temperature estimate, both Kₐ and the Schmidt number (Sc, Eq. 4) from Wanninkhof (1992) can be calculated, allowing for simulation of actual gas exchange velocities from standard conditions. The Schmidt number links the gas transfer velocity of any soluble gas (in this case carbon dioxide) from the water surface to water temperature. For more on the Schmidt number see [Wanninkhof, 2014, 1992]. The CO₂ that escapes is then subtracted from the [CO₂(aq)], stocks of each of the different hydrologic reservoirs – river, flood, and stream.

\[
T_{w} = 6.13C + (0.8 \times T_{avg})
\]
\[ (4) \quad S_c = \left(1911 - 118.11\right) \cdot T_{\text{WATER}} + \left(3.453 \cdot T_{\text{WATER}}^2\right) - \left(0.0413 \cdot T_{\text{WATER}}^3\right) \]

CO₂ evasion is therefore assumed to originate from the interplay of CO₂ solubility, relative gradient in partial pressures of CO₂ between air and water, and gas exchange kinetics. Evaporation as a flux from river and floodplain water surfaces is calculated at a daily timestep, however in order to satisfy the sensitivity of the relative gradient of partial pressures of CO₂ in the water column and atmosphere to both CO₂ inputs and evasion, the pCO₂ of water is calculated at a more refined 6 minute timestep. The daily lateral flux of CO₂ inputs to the water column are thus equally broken up into 240 (6 min.) segments per day and distributed to the pCO₂ calculation. Other relevant carbon processing pathways, such as the photochemical breakdown of riverine dissolved organic carbon, are not explicitly included here, despite the suggestion by some studies that the photochemical pathway dominate DOC processing in Arctic streams [e.g. Cory et al., 2014]. Rather, these processes are bundled into the aggregate decomposition rates used in the model, which thus include both microbial and photochemical oxidation. This is largely because it is unclear how different factors contribute to breaking down DOC in a dynamic environment and also the extent to which our DOC decomposition and CO₂ calculations implicitly include both pathways – e.g. to what extent the equations and concepts used in their calculation confound bacterial with photochemical causation, since both microbial activity and incident UV light are a function of temperature and total incident light.

2.11 Soil layer processes: turburation (Fig. 1k), adsorption (Fig. 1l)

The soil carbon module is discretised into a 32-layer scheme totalling 38m depth, which it shares with the soil thermodynamics to calculate temperature through the entire column. An aboveground snow module [Wang et al., 2013] is discretised into 3 layers of differing thickness, heat conductance and density, which collectively act as a thermodynamically-insulating intermediary between soil and atmosphere (Fig. 2a). Inputs to the three soil carbon pools are resolved only for the top 2m of the soil, where litter and DOC are exchanged with SOC in decomposition and adsorption/desorption processes. Decomposition of SOC pools, calculated in each soil layer, is dependent on soil temperature, moisture and texture [Koven et al., 2009; Zhu et al., 2016], while vertical transfer of SOC is enabled by representation of cryoturbation (downward movement of matter due to repeated freeze-thaw) in permafrost regions, and bioturbation (by soil organisms) in non-permafrost regions in terms of a diffusive flux.

Cryoturbation, given a diffusive mixing rate (Diff) of 0.001 m² yr⁻¹ [Koven et al., 2009], is possible to 3 m depth (diffusive rate declines linearly to zero from active layer bottom to 3 m). Bioturbation extends the soil column carbon concentration depth in permafrost regions from 2 m. Bioturbation is possible to 2 m depth, with a mixing rate of 0.0001 m² yr⁻¹ [Koven et al., 2013] declining to zero at 2 m (Eq. 5). In MICT-L, these vertical exchanges in the soil column are improved on. Now, we explicitly include the cryoturbation and bioturbation of both belowground litter and DOC. These were not possible in ORCHIDEE-MICT because, for the former, the belowground litter distribution was not explicitly discretised or vertically dynamic, and for the latter because DOC was not produced in prior versions. Diffusion is given by:
Where $\delta DOC_i(z)$ is the DOC in pool i at depth z, (gC m$^{-2}$ yr$^{-1}$) $IN_{DOC_i}$ the inflow of carbon to that pool (gC m$^{-2}$ yr$^{-1}$), $k_i$ the decomposition rate of that pool (d$^{-1}$), $\phi_i$ the temperature dependent rate modifier for DOC decomposition and $\text{Diff}$ the diffusion coefficient (m$^2$ yr$^{-1}$). The vertical diffusion of DOC in non-permafrost soils represented here (that is, the non-cryoturbated component) appears to be consistent with recent studies reporting an increased retention of DOC in the deepening active layer of organic soils (Zhang et al., 2017). This vertical translocation of organic carbon, whether in solid/liquid phase appears to be an important component of the high rates of SOC buildup observed at depth in deep permafrost soils.

### 2.11 Priming (Fig. 1m)

MICT-L also incorporates a scheme for the ‘priming’ of organic matter decomposition, a process in which the relative stability of SOC is impacted by the intrusion of or contact with soil of greater reactivity, resulting in enhanced rates of decomposition. This was first introduced by Guenet et al. (2016), and updated in Guenet et al. (2018). This process has shown itself to be of potentially large significance for SOC stocks and their respiration in high latitude regions, in empirical in situ and soil incubation studies (De Baets et al., 2016; Walz et al., 2017; Wild et al., 2014, 2016; Zhang et al., 2017), as well as modelling exercises (Guenet et al., 2018). Here, priming of a given soil pool is represented through the decomposition of soil carbon ($dSOC/dt$) by the following equation:

$$
\frac{dSOC}{dt} = IN_{SOC} - k \cdot \left( 1 - e^{-c \cdot FOC} \right) \cdot SOC \cdot \Theta \cdot \phi \cdot \gamma
$$

Where $IN_{SOC}$ is the carbon input to that pool, $k$ is the SOC decomposition rate (1/yr), $FOC$ (Kg) is a stock of matter interacting with this SOC pool to produce priming, $c$ is a parameter controlling this interaction, SOC is the SOC reservoir (Kg), and $\Theta$, $\phi$ and $\gamma$ the zero-dimensional moisture, temperature and soil texture rate modifiers that modulate decomposition in the code and are originally determined by the CENTURY formulation (Parton et al., 1987) and subsequently re-estimated to include priming in Guenet et al. (2016, 2018)."

The variable $FOC$ (‘fresh organic carbon’) is an umbrella term used for specifying all of the carbon pools which together constitute that carbon which is considered potential priming donor material – i.e. more labile – to a given receptor carbon pool. Thus, for the slow soil carbon pool $FOC$ incorporates the active soil carbon pool plus the above and below ground structural and metabolic litter pools, because these pools are donors to the slow pool, and considered to accelerate its turnover through priming. Importantly, previous studies with priming in ORCHIDEE employed this scheme on a version which resolves neither the vertical discretisation of the soil column nor the explicit vertical diffusion processes presented here. This is potentially significant, since the vertical diffusion of relatively reactive matter may strongly impact (accelerate) the decomposition of low reactivity matter in the deeper non-frozen horizons of high latitude soils, while the explicit discretisation of the soil column is a significant improvement in terms of the accuracy of process-representation within the column.
Due to the long residence times of the passive SOC pool, reaching full equilibrium for it itself.

Other carbon-relevant schemes included in MICT-L are: A prognostic fire routine (SPITFIRE), calibrated for the trunk version of ORCHIDEE (Yue et al., 2016) is available in our code but not activated in the simulations conducted here. As a result, we do not simulate the ~13% of Arctic riverine DOC attributed to biomass burning by Myers-Pigg et al. (2015), or the ~8% of DOC discharge to the Arctic Ocean from the same source (Stubbins et al., 2017). Likewise, a crop harvest module consistent with that in ORCHIDEE-MICT exists in MICT-L but remains deactivated for our simulations.

A module introduced in the last version of ORCHIDEE-MICT (Guimberteau et al., 2018), in which the soil thermal transfer and porosity and moisture are strongly affected by SOC concentration, is deactivated here, because it is inconsistent with the new DOC scheme. Specifically, while carbon is conserved in both MICT and MICT-L soil schemes, MICT-L introduces a new reservoir into which part of the total organic carbon in the soil –the DOC– must now go. This then lowers the SOC concentration being read by this thermix module, causing significant model artefact in soil thermodynamics and hydrology in early exploratory simulations. Ensuring compatibility of this routine with the DOC scheme will be a focal point of future developments in MICT-L. Other processes being developed for ORCHIDEE-MICT, including a high latitude peat formation (Qu et al., 2018), methane production and microbial heat generating processes that are being optimised and calibrated, are further pending additions to this particular branch of the ORCHIDEE-MICT series.

3 Soil Carbon Spinup and Simulation Protocol

The soil carbon spinup component of ORCHIDEE, which is available to both its trunk and MICT branches, was omitted from this first version of MICT-L, owing to the code burden required for ensuring compatibility with the soil carbon scheme in MICT-L. However, because we are simulating high latitude permafrost regions, having a realistic soil carbon pool at the outset of the simulations is necessary if we are to untangle the dynamics of SOC and DOC with a changing environment. Because the soil carbon spinup in ORCHIDEE-MICT is normally run over more than 10,000 years (Guimberteau et al., 2108), and because running MICT-L for this simulation period in its normal, non-spinup simulation mode would impose an unreasonable burden on computing resources, here we directly force the soil carbon output from a MICT spinup directly into the restart file of a MICT-L simulation.

A 20,000 year spinup loop over 1961-1990 (these years chosen to mimic coarsely warmer mid-Holocene climate) forced by GSWP-3 climatology, whose configuration derives directly from that used in Guimberteau et al. (2018), was thus used to replace the three soil carbon pool values from a 1-year MICT-L simulation to set their initial values. A conversion of this soil carbon from volumetric to areal units was applied, owing to different read/write standards in ORCHILEAK versus ORCHIDEE-MICT. This artificially imposed, MICT-derived SOC stock would then have to be exposed to MICT-L code, whose large differences in soil carbon module architecture as compared to MICT, would drive a search for new equilibrium soil carbon stocks.
requires a simulation length on the order of 20,000 y — again an overburden. As we are
interested primarily in DOC in this study, which derives mostly from the Active and Slow
SOC pools, the model was run until these two pools reached a quasi-steady state
equilibria (Part 2 Supplement, Fig. S1). This was done by looping over the same 30 year
cycle (1901-1930) of climate forcing data from GSWP-3 during the pre-industrial period
(see Table 1 and the first year (1901) of a prescribed vegetation map (ESA CCI Land Cover
Map, Bontemps et al., 2013)) to ensure equilbrium of DOC, dissolved CO₂ and Active
and Slow SOC pools is driven not just by a single set of environmental factors in one year
— for a total of 400 years. The parameter configuration adhered as close as possible to
that used in the original ORCHIDEE-MICT spinup simulations, to avoid excessive
equilibrium drift from the original SOC state (Fig. 3).

4 Conclusion

This first part of a two-part study has described a new branch of the high latitude
version of ORCHIDEE-MICT land surface model, in which the production, transport and
transformation of DOC and dissolved CO₂ in soils and along the inland water network of
explicitly-represented northern permafrost regions has been implemented for the first
time. Novel processes with respect to ORCHIDEE-MICT include the discretisation of
litter inputs to the soil column, the production of DOC and CO₂(aq) from organic matter
and decomposition, respectively, transport of DOC into the river routing network and its
potential mineralisation to CO₂(g) in the water column, as well as subsequent evasion
from the water surface to the atmosphere. In addition, an improved floodplains
representation has been implemented which allows for the hydrologic cycling of DOC
and CO₂ in these inundated areas. In addition to descriptions of these processes, this
paper outlines the protocols and configuration adopted for simulations using this new
model that will be used for its evaluation over the Lena river basin in the second part
of this study.

Authors’ contribution

SB coded this model version, conducted the simulations and wrote the main body of the
paper. RL gave consistent input to the coding process and made numerous code
improvements and bug fixes. BG advised on the inclusion of priming processes in the
model and advised on the study design and model configuration; DZ gave input on the
modelled soil carbon processes and model configuration. MG, AT and AD contributed to
improvements in hydrological representation and floodplain forcing data. PC oversaw all developments leading to the publication of this study. All authors contributed to suggestions regarding the final content of the study.

Figure 1: Cartoon diagram illustrating the landscape-scale emergent phenomena observed in high-latitude river systems that are captured by the processes represented in this model. Here, the terrestrial area is shown, in vertically-ascending order, as subsoil, discontinuous permafrost, continuous permafrost and the maritime boundary. Note that 'tributaries' in the Figure may be represented in the model by either the 'fast' or 'stream' pool, depending on their size. Representative soil types, their distributions and carbon concentrations are shown for the two permafrost zones, as well as the different dynamics occurring on 'flat' (left) and 'sloping' land (right) arising from their permafrost designation. Carbon exports from one subsystem to another are shown in red. The relative strength of the same processes occurring in each permafrost band are indicated by relative arrow size. Note that the high CO2 evasion in headwaters versus tributaries versus mainstem is shown here. Proposed and modelled mechanisms of soil carbon priming, adsorption and rapid metabolism are shown. The arrows QMax:Min refer to the ratio of maximum to minimum discharge at a given point in the river, the ratio indicating hydrologic volatility, whose magnitude is influenced by permafrost coverage. Soil tiles, a model construct used for modulating soil permeability and implicit/explicit decomposition, are shown to indicate the potential differences in these dynamics for the relevant permafrost zones. Note that the marine shelf sea system, as shown in the uppermost rectangle, is not simulated in this model, although our outputs can be coupled for that purpose. Letter markings mark processes of carbon flux in permafrost regions and implicitly or explicitly included in the model, and can be referred to in subsections of the Methods text. These refer to: (a) Biomass generation; (b) DOC generation and leaching; (c) Throughfall and its DOC; (d) Hydrological mobilisation of soil DOC; (e) Soil flooding; (f) Landscape routing of water and carbon; (g)
Figure 2: Carbon and water flux map for core DOC elements in model structure relating to DOC transport and transformation. (a) Summary of the differing extent of vertical discretisation of soil and snow for different processes calculated in the model. Discretisation occurs along 32 layers whose thickness increases geometrically from 0-38m. N refers to the number of layers, SWE=snow water equivalent, $S_n$ = Snow layer n. Orange layers indicate the depth to which diffusive carbon (turbation) fluxes occur. (b) Conceptual map of the production, transfer and transformation of carbon in its vertical and lateral (i.e., hydrological) flux as calculated in the model. Red boxes indicate meta-reservoirs of carbon, black boxes the actual pools as they exist in the model. Black arrows indicate carbon fluxes between pools, dashed red arrows give carbon loss as $\text{CO}_2$, green arrows highlight the fractional distribution of DOC to SOC (no carbon loss incurred in this transfer), a feature of this model. For a given temperature (5°C) and soil clay fraction, the fractional fluxes between pools are given for each flux, while residence times for each pool ($\tau$) are in each box. The association of carbon dynamics with the hydrological module are shown by the blue arrows. Blue coloured boxes illustrate the statistical sequence which activates the boolean floodplains module. Note that for
readability, the generation and lateral flux of dissolved CO$_2$ is omitted from this diagram, but is described at length in the Methods section.

**Figure 3:** Flow diagram illustrating the step-wise stages required to implement the model’s soil carbon stock prior to conducting transient, historical simulations.
